This option indicates that operation should be performed on the screen-independent resource property (RESOURCE_MANAGER), as well as the screen-specific property (SCREEN_RESOURCES) on every screen of the display. For example, when used in conjunction with `-query`, the contents of all properties are output. For `-load`, `-override`, and `-merge`, the input file is processed once for each screen. The resources that occur in common in the output for every screen are collected, and these are applied as the screen-independent resources. The remaining resources are applied for each individual per-screen property. This the default mode of operation.

<code>-global</code>	This option indicates that the operation should only be performed on the screen-independent <code>RESOURCE_MANAGER</code> property.
<code>-screen</code>	This option indicates that the operation should only be performed on the <code>SCREEN_RESOURCES</code> property of the default screen of the display.
<code>-screens</code>	This option indicates that the operation should be performed on the <code>SCREEN_RESOURCES</code> property of each screen of the display. For <code>-load</code> , <code>-override</code> , and <code>-merge</code> , the input file is processed for each screen.
<code>-n</code>	This option indicates that changes to the specified properties (when used with <code>-load</code> , <code>-override</code> , or <code>-merge</code>) or to the resource file (when used with <code>-edit</code>) should be shown on the standard output, but should not be performed.
<code>-quiet</code>	This option indicates that warning about duplicate entries should not be displayed.
<code>-cpp filename</code>	This option specifies the pathname of the C preprocessor program to be used. Although <code>xrdp</code> was designed to use CPP, any program that acts as a filter and accepts the <code>-D</code> , <code>-I</code> , and <code>-U</code> options may be used.
<code>-nocpp</code>	This option indicates that <code>xrdp</code> should not run the input file through a preprocessor before loading it into properties.
<code>-symbols</code>	This option indicates that the symbols that are defined for the preprocessor should be printed onto the standard output.
<code>-query</code>	This option indicates that the current contents of the specified properties should be printed onto the standard output. Note that since preprocessor commands in the input resource file are part of the input file, not part of the property, they won't appear in the output from this option. The <code>-edit</code> option can be used to merge the contents of properties back into the input resource file without damaging preprocessor commands.
<code>-load</code>	This option indicates that the input should be loaded as the new value of the specified properties, replacing whatever was there; that is, the old contents are removed. This is the default action.
<code>-override</code>	This option indicates that the input should be added to, instead of replacing, the current contents of the specified properties. New entries override previous entries.
<code>-merge</code>	This option indicates that the input should be merged and lexicographically sorted with, instead of replacing, the current contents of the specified properties.
<code>-remove</code>	This option indicates that the specified properties should be removed from the server.
<code>-retain</code>	This option indicates that the server should be instructed not to reset if <code>xrdp</code> is the first client. This should never be necessary under normal conditions, since <code>xdm</code> and <code>xinit</code> always act as the first client.
<code>-edit filename</code>	This option indicates that the contents of the specified properties should be edited into the given file, replacing any values already listed there. This allows you to put changes that you have made to your defaults back into your resource file, preserving any comments or preprocessor lines.

`-backup string`

This option specifies a suffix to be appended to the filename used with `-edit` to generate a backup file.

`-Dname[=value]`

This option is passed through to the preprocessor and is used to define symbols for use with conditionals such as `#ifdef`.

`-Uname`

This option is passed through to the preprocessor and is used to remove any definitions of this symbol.

`-Idirectory`

This option is passed through to the preprocessor and is used to specify a directory to search for files that are referenced with `#include`.

FILES

Generalizes `-.Xdefaults` files

SEE ALSO

`x(1)`, Xlib Resource Manager documentation, `xt` resource documentation

ENVIRONMENT

`DISPLAY`

To figure out which display to use.

BUGS

The default for no arguments should be to query, not to overwrite, so that it is consistent with other programs.

X Version 11 Release 6

xrefresh

`xrefresh`—Refresh all or part of an X screen

SYNOPSIS

`xrefresh [-option ...]`

DESCRIPTION

`xrefresh` is a simple X program that causes all or part of your screen to be repainted. This is useful when system messages have messed up your screen. `xrefresh` maps a window on top of the desired area of the screen and then immediately unmaps it, causing refresh events to be sent to all applications. By default, a window with no background is used, causing all applications to repaint smoothly. However, the various options can be used to indicate that a solid background (of any color) or the root window background should be used instead.

ARGUMENTS

`-white`

Use a white background. The screen just appears to flash quickly, and then repaint.

`-black`

Use a black background (in effect, turning off all of the electron guns to the tube). This can be somewhat disorienting as everything goes black for a moment.

`-solid color`

Use a solid background of the specified color. Try green.

`-root`

Use the root window background.

-none
 -geometry WxH+X+Y
 -display display

This is the default. All of the windows simply repaint.
 Specifies the portion of the screen to be repainted; see `x(1)`.
 This argument allows you to specify the server and screen to refresh; see `x(1)`.

X DEFAULTS

The `xrefresh` program uses the routine `XGetDefault(3X)` to read defaults, so its resource names are all capitalized.

Black, White, Solid, None, Root
 Geometry

Determines what sort of window background to use
 Determines the area to refresh. Not very useful.

ENVIRONMENT

DISPLAY

To get default host and display number.

SEE ALSO

`x(1)`

BUGS

It should have just one default type for the background.

X Version 11 Release 6

Xserver

`xserver`—X Window System display server

SYNOPSIS

`X [option ...]`

DESCRIPTION

`x` is the generic name for the X Window System display server. It is frequently a link or a copy of the appropriate server binary for driving the most frequently used server on a given machine.

STARTING THE SERVER

The `x` server is usually started from the X Display Manager program `xdm(1)`. This utility is run from the system boot files and takes care of keeping the server running, prompting for usernames and passwords, and starting up the user sessions.

Installations that run more than one window system may need to use the `xinit(1)` utility instead of `xdm`. However, `xinit` is to be considered a tool for building startup scripts and is not intended for use by end users. Site administrators are strongly urged to use `xdm`, or build other interfaces for novice users.

The `x` server may also be started directly by the user, though this method is usually reserved for testing and is not recommended for normal operation. On some platforms, the user must have special permission to start the `x` server, often because access to certain devices. (For example, `/dev/mouse` is restricted.)

When the `x` server starts up, it typically takes over the display. If you are running on a workstation whose console is the display, you may not be able to log into the console while the server is running.

OPTIONS

All of the `x` servers accept the following command-line options:

<code>:displaynumber</code>	The <code>x</code> server runs as the given <code>displaynumber</code> , which by default is 0. If multiple <code>x</code> servers are to run simultaneously on a host, each must have a unique display number. See the “Display Names” subsection of the <code>x(1)</code> manual page to learn how to specify which display number clients should try to use.
<code>-a number</code>	Sets pointer acceleration (that is, the ratio of how much is reported to how much the user actually moved the pointer).
<code>-ac</code>	Disables host-based access control mechanisms. Enables access by any host, and permits any host to modify the access control list. Use with extreme caution. This option exists primarily for running test suites remotely.
<code>-audit level</code>	Sets the audit trail level. The default level is 1, meaning only connection rejections are reported. Level 2 additionally reports all successful connections and disconnects. Level 0 turns off the audit trail. Audit lines are sent as standard error output.
<code>-auth authorization-file</code>	Specifies a file which contains a collection of authorization records used to authenticate access. See also the <code>xdm</code> and <code>Xsecurity</code> manual pages.
<code>bc</code>	Disables certain kinds of error checking, for bug compatibility with previous releases (for example, to work around bugs in R2 and R3 <code>xterms</code> and toolkits). Deprecated.
<code>-bs</code>	Disables backing store support on all screens.
<code>-c</code>	Turns off key-click.
<code>c volume</code>	Sets key-click volume (allowable range: 0–100).
<code>-cc class</code>	Sets the <code>visual</code> class for the root window of color screens. The class numbers are as specified in the <code>x</code> protocol. Not obeyed by all servers.
<code>-co filename</code>	Sets name of RGB color database. The default is <code><XRoot>/lib/X11/rgb</code> , where <code><Xroot></code> refers to the root of the X11 install tree.
<code>-config filename</code>	Reads more options from the given file. Options in the file may be separated by newlines if desired. If a <code>#</code> character appears on a line, all characters between it and the next newline are ignored, providing a simple commenting facility. The <code>-config</code> option itself may appear in the file.
<code>-core</code>	Causes the server to generate a core dump on fatal errors.
<code>-dpi resolution</code>	Sets the resolution of the screen, in dots per inch. To be used when the server cannot determine the screen size from the hardware.
<code>-deferglyphs whichfonts</code>	Specifies the types of fonts for which the server should attempt to use deferred glyph loading. <code>whichfonts</code> can be <code>all</code> (all fonts), <code>none</code> (no fonts), or <code>16</code> (16-bit fonts only).
<code>-f volume</code>	Sets beep (bell) volume (allowable range: 0–100).
<code>-fc cursorFont</code>	Sets default cursor font.
<code>-fn font</code>	Sets the default font.

-fp fontPath	Sets the search path for fonts. This path is a comma-separated list of directories that the X server searches for font databases. <code>-help</code> prints a usage message.
-I	Causes all remaining command-line arguments to be ignored.
-kb	Disables the <code>XKEYBOARD</code> extension if present.
-p minutes	Sets screen saver pattern cycle time in minutes.
-pn	Permits the server to continue running if it fails to establish all of its well-known sockets (connection points for clients), but establishes at least one.
-r	Turns off auto-repeat.
r	Turns on auto-repeat.
-s minutes	Sets screen saver time-out time in minutes.
-su	Disables save under support on all screens.
-t number	Sets pointer acceleration threshold in pixels (that is, sets after how many pixels pointer acceleration should take effect).
-terminate	Causes the server to terminate at server reset, instead of continuing to run.
-to seconds	Sets default connection time-out in seconds.
-tst	Disables all testing extensions (for example, <code>XTEST</code> , <code>XTrap</code> , <code>XTestExtension1</code>).
ttyxx	Ignored, for servers started the ancient way (from <code>init</code>).
v	Sets video-off screen saver preference.
-v	Sets video-on screen saver preference.
-wm	Forces the default backing-store of all windows to be <code>WhenMapped</code> . This is a backdoor way of getting backing-store to apply to all windows. Although all mapped windows will have backing-store, the backing-store attribute value reported by the server for a window will be the last value established by a client. If it has never been set by a client, the server will report the default value, <code>NotUseful</code> . This behavior is required by the <code>x</code> protocol, which allows the server to exceed the client's backing-store expectations but does not provide a way to tell the client that it is doing so.
-x extension	Loads the specified extension at <code>init</code> . This is a no-op for most implementations.

SERVER DEPENDENT OPTIONS

Some `x` servers accept the following options:

-ld kilobytes	Sets the data space limit of the server to the specified number of kilobytes. A value of zero makes the data size as large as possible. The default value of <code>-1</code> leaves the data space limit unchanged.
-lf files	Sets the number-of-open-files limit of the server to the specified number. A value of zero makes the limit as large as possible. The default value of <code>-1</code> leaves the limit unchanged.
-ls kilobytes	Sets the stack space limit of the server to the specified number of kilobytes. A value of zero makes the stack size as large as possible. The default value of <code>-1</code> leaves the stack space limit unchanged.

<code>-logo</code>	Turns on the X Window System logo display in the screen saver. There is currently no way to change this from a client.
<code>nologo</code>	Turns off the X Window System logo display in the screen saver. There is currently no way to change this from a client.

XDMCP OPTIONS

`x` servers that support XDMCP have the following options. (See the *X Display Manager Control Protocol* specification for more information.)

<code>-query host-name</code>	Enable XDMCP and send <code>Query</code> packets to the specified host.
<code>-broadcast</code>	Enable XDMCP and broadcast <code>BroadcastQuery</code> packets to the network. The first responding display manager will be chosen for the session.
<code>-indirect host-name</code>	Enable XDMCP and send <code>IndirectQuery</code> packets to the specified host.
<code>-port port-num</code>	Use an alternate port number for XDMCP packets. Must be specified before any <code>-query</code> , <code>-broadcast</code> , or <code>-indirect</code> options.
<code>-class display-class</code>	XDMCP has an additional display qualifier used in resource lookup for display-specific options. This option sets that value; by default it is <code>MIT-Unspecified</code> (not a very useful value).
<code>-cookie xdm-auth-bits</code>	When testing <code>XDM-AUTHENTICATION-1</code> , a private key is shared between the server and the manager. This option sets the value of that private data (not that it is very private, being on the command line!).
<code>-displayID display-id</code>	Yet another XDMCP-specific value, this one allows the display manager to identify each display so that it can locate the shared key.

XKEYBOARD OPTIONS

`x` servers that support the `XKEYBOARD` extension accept the following options:

<code>-xkbdir directory</code>	Base directory for keyboard layout files
<code>-xkbmap filename</code>	Keyboard description to load on startup
<code>[+-]accessx</code>	Enable(+) or disable(-) AccessX key sequences
<code>-ar1 milliseconds</code>	Sets the length of time in milliseconds that a key must be depressed before auto-repeat starts
<code>-ar2 milliseconds</code>	Sets the length of time in milliseconds that should elapse between auto-repeat-generated keystrokes

Many servers also have device-specific command-line options. See the manual pages for the individual servers for more details.

NETWORK CONNECTIONS

The `x` server supports client connections via a platform-dependent subset of the following transport types: TCPIP, UNIX Domain sockets, DECnet, and several varieties of SVR4 local connections. See the “Display Names” subsection of the `x(1)` manual page to learn how to specify which transport type clients should try to use.

SECURITY

The `x` server implements a platform-dependent subset of the following authorization protocols: `-MIT-MAGICCOOKIE-1`, `XDM-AUTHORIZATION-1`, `SUN-DES-1`, and `MIT-KERBEROS-5`. See the `xsecurity(1)` manual page for information on the operation of these protocols.

Authorization data required by the preceding protocols is passed to the server in a private file named with the `-auth` command-line option. Each time the server is about to accept the first connection after a reset (or when the server is starting), it reads this file. If this file contains any authorization records, the local host is not automatically allowed access to the server, and only clients that send one of the authorization records contained in the file in the connection setup information will be allowed access. See the `xau` manual page for a description of the binary format of this file. See `xauth(1)` for maintenance of this file, and distribution of its contents to remote hosts.

The `x` server also uses a host-based access control list for deciding whether or not to accept connections from clients on a particular machine. If no other authorization mechanism is being used, this list initially consists of the host on which the server is running as well as any machines listed in the file `/etc/Xn.hosts`, where `n` is the display number of the server. Each line of the file should contain either an Internet hostname (for example `expo.lcs.mit.edu`) or a DECnet hostname in double colon format (for example, `hydra::`). There should be no leading or trailing spaces on any lines. For example,

```
joesworkstation
corporate.company.com
star::
bigcpu::
```

Users can add or remove hosts from this list and enable or disable access control using the `xhost` command from the same machine as the server.

The `x` protocol intrinsically does not have any notion of window operation permissions or place any restrictions on what a client can do; if a program can connect to a display, it has full run of the screen. Sites that have better authentication and authorization systems might wish to make use of the hooks in the libraries and the server to provide additional security models.

SIGNALS

The `x` server attaches special meaning to the following signals:

SIGHUP

This signal causes the server to close all existing connections, free all resources, and restore all defaults. It is sent by the display manager whenever the main user's main application (usually an `xterm` or window manager) exits to force the server to clean up and prepare for the next user.

SIGTERM

This signal causes the server to exit cleanly.

SIGUSR1

This signal is used quite differently from either of the above. When the server starts, it checks to see if it has inherited `SIGUSR1` as `SIG_IGN` instead of the usual `SIG_DFL`. In this case, the server sends a `SIGUSR1` to its parent process after it has set up the various connection schemes. `xdm` uses this feature to recognize when connecting to the server is possible.

FONTS

The `x` server can obtain fonts from directories or from font servers. The list of directories and font servers the `x` server uses when trying to open a font is controlled by the font path.

The default font path is

```
<XRoot>/lib/X11/fonts/misc/,
<XRoot>/lib/X11/fonts/Speedo/,
<XRoot>/lib/X11/fonts/Type1/,
<XRoot>/lib/X11/fonts/75dpi/,
<XRoot>/lib/X11/fonts/100dpi/
```

where `<XRoot>` refers to the root of the X11 install tree.

The font path can be set with the `-fp` option or by `xset(1)` after the server has started.

FILES

```

/etc/Xn.hosts
<XRoot>/lib/X11/fonts/misc
<XRoot>/lib/X11/fonts/75dpi
<XRoot>/lib/X11/fonts/100dpi
<XRoot>/lib/X11/fonts/Speedo
<XRoot>/lib/X11/fonts/Type1
<XRoot>/lib/X11/fonts/PEX
<XRoot>/lib/X11/rgb.txt
/tmp/.X11-unix/Xn
/tmp/rcXn
/usr/adm/Xnmsgs
<XRoot>/lib/X11/xdm/xdm-errors

```

Note: <XRoot> refers to the root of the X11 install tree.

Initial access control list for display number *n*

Bitmap font directories

Outline font directories

PEX font directories

Color database

UNIX domain socket for display number *n*

Kerberos 5 replay cache for display number *n*

Error log file for display number *n* if run from `init(8)`

Default error log file if the server is run from `xdm(1)`

X Version 11 Release 6

xset

`xset`—User preference utility for X

SYNOPSIS

```

xset [-display display] [-b] [b on/off] [b [volume [pitch [duration]]] [[-]bc]
[-c] [c on/off] [c [volume]] [[-+]fp[+]=] path[,path[,...]]] [fp default]
[fp rehash] [[-]led [integer]] [led on/off] [m[mouse] [accel_mult[accel_div]
[threshold]]] [m[mouse] default] [p pixel color] [[-]r [keycode]] [r on/off]
[s [length [period]]] [s blank/noblink] [s expose/noexpose] [s on/off]
[s default] [s activate] [s reset] [q]

```

DESCRIPTION

This program is used to set various user preference options of the display.

OPTIONS

`-display display`

`b`

This option specifies the server to use; see `x(1)`.

The `b` option controls bell volume, pitch, and duration. This option accepts up to three numerical parameters, a preceding dash (`-`), or an `on/off` flag. If no parameters are given, or the `on` flag is used, the system defaults will be used. If the dash or `off` is given, the bell will be turned off. If only one numerical parameter is given, the bell volume will be set to that value, as a percentage of its maximum. Likewise, the second numerical parameter specifies the bell pitch, in hertz, and the third numerical parameter specifies the duration in milliseconds. Note that not all hardware can vary the bell characteristics. The `x` server will set the characteristics of the bell as closely as it can to the user's specifications.

`bc`

The `bc` option controls bug compatibility mode in the server, if possible; a preceding dash (`-`) disables the mode; otherwise, the mode is enabled. Various pre-R4 clients pass illegal values in some protocol requests, and pre-R4 servers did not correctly generate errors in these cases. Such clients, when run against an R4 server, will terminate abnormally or otherwise fail to operate correctly. Bug compatibility mode explicitly reintroduces certain bugs into the `x` server, so that many such clients can still be run. This mode should be used with care; new application development should be done with this mode disabled. The server must support the MIT-SUNDRY-NONSTANDARD protocol extension in order for this option to work.

`c`

The `c` option controls key click. This option can take an optional value, a preceding dash (`-`), or an `on/off` flag. If no parameter or the `on` flag is given, the system defaults will be used. If the dash or `off` flag is used, key click will be disabled. If a value from 0 to 100 is given, it is used to indicate volume, as a percentage of the maximum. The `x` server will set the volume to the nearest value that the hardware can support.

`fp= path,...`

The `fp=` sets the font path to the entries given in the `path` argument. The entries are interpreted by the server, not by the client. Typically, they are directory names or font server names, but the interpretation is server-dependent.

`fp default`

The `default` argument causes the font path to be reset to the server's default.

`fp rehash`

The `rehash` argument resets the font path to its current value, causing the server to reread the font databases in the current font path. This is generally only used when adding new fonts to a font directory (after running `mkfontdir` to re-create the font database).

`-fp or fp-`

The `-fp` and `fp-` options remove elements from the current font path. They must be followed by a comma-separated list of entries.

`fp` OR `fp`

This `fp` and `fp` options prepend and append elements to the current font path, respectively. They must be followed by a comma-separated list of entries.

`led`

The `led` option controls the keyboard LEDs. This controls the turning on or off of one or all of the LEDs. It accepts an optional integer, a preceding dash (-) or an `on/off` flag. If no parameter or the `on` flag is given, all LEDs are turned on. If a preceding dash or the flag `off` is given, all LEDs are turned off. If a value between 1 and 32 is given, that LED will be turned on or off depending on the existence of a preceding dash. A common LED that can be controlled is the Caps Lock LED. `xset led 3` would turn led #3 on. `xset -led 3` would turn it off. The particular LED values may refer to different LEDs on different hardware.

`m`

The `m` option controls the mouse parameters. The parameters for the mouse are `acceleration` and `threshold`. The acceleration can be specified as an integer, or as a simple fraction. The mouse, or whatever pointer the machine is connected to, will go `acceleration` times as fast when it travels more than `threshold` pixels in a short time. This way, the mouse can be used for precise alignment when it is moved slowly, yet it can be set to travel across the screen in a flick of the wrist when desired. One or both parameters for the `m` option can be omitted, but if only one is given, it will be interpreted as the acceleration. If no parameters or the flag `default` is used, the system defaults will be set.

`p`

The `p` option controls pixel color values. The parameters are the color map entry number in decimal, and a color specification. The root background colors may be changed on some servers by altering the entries for `BlackPixel` and `WhitePixel`. Although these are often 0 and 1, they need not be. Also, a server may choose to allocate those colors privately, in which case an error will be generated. The map entry must not be a read-only color, or an error will result.

`r`

The `r` option controls the auto-repeat. If a preceding dash or the `off` flag is used, auto-repeat will be disabled. If no parameters or the `on` flag is used, auto-repeat will be enabled. If a specific keycode is specified as a parameter, auto-repeat for that keycode is enabled or disabled.

`s`

The `s` option lets you set the screen saver parameters. This option accepts up to two numerical parameters, a `blank/noblank` flag, an `expose/noexpose` flag, an `on/off` flag, an `activate/reset` flag, or the `default` flag. If no parameters or the `default` flag is used, the system will be set to its default screen saver characteristics. The `on/off` flags simply turn the screen saver functions on or off. The `activate` flag forces activation of screen saver even if the screen saver had been turned off. The `reset` flag forces deactivation of screen saver if it is active. The `blank` flag sets the preference to blank the video (if the hardware can do so) rather than display a background pattern, while `noblank` sets the preference to display a pattern rather than blank the video. The `expose` flag sets the preference to allow window exposures (the server can

freely discard window contents), while `noexpose` sets the preference to disable screen saver unless the server can regenerate the screens without causing exposure events. The `length` and `period` parameters for the screen saver function determines how long the server must be inactive for screen saving to activate, and the `period` to change the background pattern to avoid burn in. The arguments are specified in seconds. If only one numerical parameter is given, it will be used for the `length`.

q

The `q` option gives you information on the current settings.

These settings will be reset to default values when you log out.

Note that not all `x` implementations are guaranteed to honor all of these options.

X Version 11 Release 6

xsetroot

`xsetroot`—Root window parameter setting utility for `x`

SYNOPSIS

```
xsetroot [-help] [-def] [-display display] [-cursor cursorfile maskfile]
[-cursor_name cursorname] [-bitmap filename] [-mod x y] [-gray] [-grey]
[-fg color] [-bg color] [-rv] [-solid color] [-name string]
```

DESCRIPTION

The `setroot` program allows you to tailor the appearance of the background (root) window on a workstation display running `x`. Normally, you experiment with `xsetroot` until you find a personalized look that you like, then put the `xsetroot` command that produces it into your `x` startup file. If no options are specified, or if `-def` is specified, the window is reset to its default state. The `-def` option can be specified along with other options and only the nonspecified characteristics will be reset to the default state.

Only one of the background color/tiling changing options (`-solid`, `-gray`, `-grey`, `-bitmap`, and `-mod`) may be specified at a time.

OPTIONS

The various options are as follows:

`-help`

Print a usage message and exit.

`-def`

Reset unspecified attributes to the default values. (Restores the background to the familiar gray mesh and the cursor to the hollow `x` shape.)

`-cursor cursorfile maskfile`

This lets you change the pointer cursor to whatever you want when the pointer cursor is outside of any window. Cursor and mask files are bitmaps (little pictures), and can be made with the `bitmap(1)` program. You probably want the mask file to be all black until you get used to the way masks work.

`-cursor_name cursorname`

This lets you change the pointer cursor to one of the standard cursors from the cursor font. Refer to Appendix B of the `x` protocol for the names (except that the `xc` prefix is elided for this option).

`-bitmap filename`

Use the bitmap specified in the file to set the window pattern. You can make your own bitmap files (little pictures) using the `bitmap(1)` program. The entire background will be made up of repeated “tiles” of the bitmap.

`-mod x y`

This is used if you want a plaid-like grid pattern on your screen. `x` and `y` are integers ranging from 1 to 16. Try the different combinations. Zero and negative numbers are taken as 1.

`-gray`

Make the entire background gray. (Easier on the eyes.)

`-grey`

Make the entire background grey.

`-fg color`

Use `color` as the foreground color. Foreground and background colors are meaningful only in combination with `-cursor`, `-bitmap`, or `-mod`.

`-bg color`

Use `color` as the background color.

`-rv`

This exchanges the foreground and background colors. Normally the foreground color is black and the background color is white.

`-solid color`

This sets the background of the root window to the specified color. This option is only useful on color servers.

`-name string`

Set the name of the root window to `string`. There is no default value. Usually a name is assigned to a window so that the window manager can use a text representation when the window is iconified. This option is unused because you can't iconify the background.

`-display display`

Specifies the server to connect to; see `x(1)`.

X Version 11 Release 6

Xsm

`xsm`—X Session Manager

SYNOPSIS

```
xsm [-display display] [-session sessionName] [-verbose]
```

DESCRIPTION

`xsm` is a session manager. A session is a group of applications, each of which has a particular state. `xsm` allows you to create arbitrary sessions. For example, you might have a `light` session, a `development` session, or an `xterminal` session. Each session can have its own set of applications. Within a session, you can perform a `checkpoint` to save application state, or a `shutdown` to save state and exit the session. When you log back in to the system, you can load a specific session, and you can delete sessions you no longer want to keep.

Some session managers simply allow you to manually specify a list of applications to be started in a session. `xsm` is more powerful because it lets you run applications and have them automatically become part of the session. On a simple level, `xsm` is useful because it gives you this ability to easily define which applications are in a session. The true power of `xsm`, however, can be taken advantage of when more and more applications learn to save and restore their state.

OPTIONS

<code>-display display</code>	Causes <code>xsm</code> to connect to the specified X display.
<code>-session sessionName</code>	Causes <code>xsm</code> to load the specified session, bypassing the session menu.
<code>-verbose</code>	Turns on debugging information.

SETUP

.xsession FILE

Using `xsm` requires a change to your `.xsession` file:

The last program executed by your `.xsession` file should be `xsm`. With this configuration, when the user chooses to shut down the session using `xsm`, the session will truly be over.

Because the goal of the session manager is to restart clients when logging into a session, your `.xsession` file, in general, should not directly start up applications. Rather, the applications should be started within a session. When `xsm` shuts down the session, `xsm` will know to restart these applications. Note, however, that there are some types of applications that are not “session aware”. `xsm` enables you to manually add these applications to your session. (See the subsection titled “Client List.”)

SM_SAVE_DIR ENVIRONMENT VARIABLE

If the `SM_SAVE_DIR` environment variable is defined, `xsm` will save all configuration files in this directory. Otherwise, they will be stored in the user’s home directory. Session-aware applications are also encouraged to save their checkpoint files in the `SM_SAVE_DIR` directory, although the user should not depend on this convention.

DEFAULT STARTUP APPLICATIONS

The first time `xsm` is started, it will need to locate a list of applications to start up. For example, this list might include a window manager, a session management proxy, and an `xterm`. `xsm` will first look for the file `.xsmstartup` in the user’s home directory. If that file does not exist, it will look for the `system.xsm` file that was set up at installation time. Note that `xsm` provides a `failsafe` option when the user chooses a session to start up. The `failsafe` option simply loads the default applications described above.

Each line in the startup file should contain a command to start an application. A sample startup file might look this:

```
<start of file>
twm
smproxy
xterm
<end of file>
```

STARTING A SESSION

When `xsm` starts up, it first checks to see if the user previously saved any sessions. If no saved sessions exist, `xsm` starts up a set of default applications (as described above in the subsection titled “Default Startup Applications”). If at least one session exists, a Session menu is presented. The `[-session sessionName]` option forces the specified session to be loaded, bypassing the session menu.

THE SESSION MENU

The Session menu presents the user with a list of sessions to choose from. The user can change the currently selected session with the mouse, or by using the up and down arrows on the keyboard. Note that sessions that are locked (that is, running on a different display) cannot be loaded or deleted.

The following operations can be performed from the Session menu:

Load Session	Pressing this button will load the currently selected session. Alternatively, hitting the Return key will also load the currently selected session, or the user can double-click a session from the list.
Delete Session	This operation will delete the currently selected session, along with all of the application checkpoint files associated with the session. After pressing this button, the user will be asked to press the button a second time in order to confirm the operation.
Default/Fail Safe	<code>xsm</code> will start up a set of default applications (as described earlier in the section titled “Default Startup Applications”). This is useful when the user wants to start a fresh session, or if the session configuration files were corrupted and the user wants a failsafe session.
Cancel	Pressing this button will cause <code>xsm</code> to exit. It can also be used to cancel a Delete Session operation.

CONTROLLING A SESSION

After `xsm` determines which session to load, it brings up its main window, then starts up all applications that are part of the session. The title bar for the session manager’s main window will contain the name of the session that was loaded.

The following options are available from `xsm`’s main window:

Client List	<p>Pressing this button brings up a window containing a list of all clients that are in the current session. For each client, the host machine that the client is running on is presented. As clients are added and removed from the session, this list is updated to reflect the changes. The user is able to control how these clients are restarted.</p> <p>By pressing the View Properties button, the user can view the session management properties associated with the currently selected client.</p> <p>By pressing the Clone button, the user can start a copy of the selected application.</p> <p>By pressing the Kill Client button, the user can remove a client from the session. By selecting a restart hint from the Restart Hint menu, the user can control the restarting of a client. The following hints are available:</p> <ul style="list-style-type: none"> ■ The Restart If Running hint indicates that the client should be restarted in the next session if it is connected to the session manager at the end of the current session. ■ The Restart Anyway hint indicates that the client should be restarted in the next session even if it exits before the current session is terminated. ■ The Restart Immediately hint is similar to the Restart Anyway hint, but in addition, the client is meant to run continuously. If the client exits, the session manager will try to restart it in the current session. ■ The Restart Never hint indicates that the client should not be restarted in the next session.
-------------	--

Session Log...

Checkpoint

Note that all X applications may not be session aware. Applications that are not session aware are ones that do not support the X Session Management Protocol or they cannot be detected by the Session Management Proxy. (See the subsection titled “The Proxy.”). `xsm` allows the user to manually add such applications to the session. The bottom of the Client List window contains a text entry field into which application commands can be typed. Each command should go on its own line. This information will be saved with the session at checkpoint or shutdown time. When the session is restarted, `xsm` will restart these applications in addition to the regular session aware applications. Pressing the Done button removes the Client List window.

The Session Log window presents useful information about the session. For example, when a session is restarted, all of the restart commands will be displayed in the log window.

By performing a checkpoint, all applications that are in the session are asked to save their state. Not every application will save its complete state, but at a minimum, the session manager is guaranteed that it will receive the command required to restart the application (along with all command-line options). A window manager participating in the session should guarantee that the applications will come back up with the same window configurations.

If the session being checkpointed was never assigned a name, the user will be required to specify a session name. Otherwise, the user can perform the checkpoint using the current session name, or a new session name can be specified. If the session name specified already exists, the user will be given the opportunity to specify a different name or to overwrite the already existing session. Note that a session that is locked can not be overwritten.

When performing a checkpoint, the user must specify a `Save Type` that informs the applications in the session how much state they should save.

The `Local` type indicates that the application should save enough information to restore the state as seen by the user. It should not affect the state as seen by other users. For example, an editor would create a temporary file containing the contents of its editing buffer, the location of the cursor, and so on.

The `Global` type indicates that the application should commit all of its data to permanent, globally accessible storage. For example, the editor would simply save the edited file.

The `Both` type indicates that the application should do both of these. For example, the editor would save the edited file, then create a temporary file with information such as the location of the cursor, and so on.

In addition to the `Save Type`, the user must specify an `Interact Style`.

The `None` type indicates that the application should not interact with the user while saving state.

Shutdown

The `Errors` type indicates that the application may interact with the user only if an error condition arises.

The `Any` type indicates that the application may interact with the user for any purpose. Note that `xsm` will only allow one application to interact with the user at a time.

After the checkpoint is completed, `xsm` will, if necessary, display a window containing the list of applications that did not report a successful save of state.

A shutdown provides all of the options found in a checkpoint, but, in addition, can cause the session to exit. Note that if the interaction style is `Errors` or `Any`, the user may cancel the shutdown. The user may also cancel the shutdown if any of the applications report an unsuccessful save of state. The user may choose to shut down the session with or without performing a checkpoint.

THE PROXY

Because not all applications have been ported to support the X Session Management Protocol, a proxy service exists to enable “old” clients to work with the session manager. In order for the proxy to detect an application joining a session, one of the following must be true:

- The application maps a top-level window containing the `WM_CLIENT_LEADER` property. This property provides a pointer to the client leader window that contains the `WM_CLASS`, `WM_NAME`, `WM_COMMAND`, and `WM_CLIENT_MACHINE` properties.
- or
- The application maps a top-level window that does not contain the `WM_CLIENT_LEADER` property. However, this top-level window contains the `WM_CLASS`, `WM_NAME`, `WM_COMMAND`, and `WM_CLIENT_MACHINE` properties.

An application that supports the `WM_SAVE_YOURSELF` protocol will receive a `WM_SAVE_YOURSELF` client message each time the session manager issues a checkpoint or shutdown. This allows the application to save state. If an application does not support the `WM_SAVE_YOURSELF` protocol, then the proxy will provide enough information to the session manager to restart the application (using `WM_COMMAND`), but no state will be restored.

REMOTE APPLICATIONS

`xsm` requires a remote execution protocol in order to restart applications on remote machines. Currently, `xsm` supports the `rstart` protocol. In order to restart an application on remote machine `X`, machine `X` must have `rstart` installed. In the future, additional remote execution protocols may be supported.

xstdcmap

xstdcmap—X standard colormap utility

SYNOPSIS

```
xstdcmap [-all] [-best] [-blue] [-default] [-delete map] [-display display]
[-gray] [-green] [-help] [-red] [-verbose]
```

DESCRIPTION

The `xstdcmap` utility can be used to selectively define standard colormap properties. It is intended to be run from a user's X startup script to create standard colormap definitions in order to facilitate sharing of scarce colormap resources among clients. Where at all possible, colormaps are created with read-only allocations.

OPTIONS

The following options may be used with `xstdcmap`:

`-all`

This option indicates that all six standard colormap properties should be defined on each screen of the display. Not all screens will support visuals under which all six standard colormap properties are meaningful. `xstdcmap` will determine the best allocations and visuals for the colormap properties of a screen. Any previously existing standard colormap properties will be replaced.

`-best`

This option indicates that the `RGB_BEST_MAP` should be defined.

`-blue`

This option indicates that the `RGB_BLUE_MAP` should be defined.

`-default`

This option indicates that the `RGB_DEFAULT_MAP` should be defined.

`-delete map`

This option specifies that a specific standard colormap property, or all such properties, should be removed. `map` may be one of: `default`, `best`, `red`, `green`, `blue`, `gray`, or `all`.

`-display display`

This option specifies the host and display to use; see `x(1)`.

`-gray`

This option indicates that the `RGB_GRAY_MAP` should be defined.

`-green`

This option indicates that the `RGB_GREEN_MAP` should be defined.

`-help`

This option indicates that a brief description of the command-line arguments should be printed on the standard error. This will be done whenever an unhandled argument is given to `xstdcmap`.

`-red`

This option indicates that the `RGB_RED_MAP` should be defined.

`-verbose`

This option indicates that `xstdcmap` should print logging information as it parses its input and defines the standard colormap properties.

X Version 11 Release 6

xterm

xterm—Terminal emulator for X

SYNOPSIS

xterm [-toolkitoption ...] [-option ...]

DESCRIPTION

The `xterm` program is a terminal emulator for the X Window System. It provides DEC VT102- and Tektronix 4014-compatible terminals for programs that can't use the window system directly. If the underlying operating system supports terminal resizing capabilities (for example, the `SIGWINCH` signal in systems derived from 4.3bsd), `xterm` will use the facilities to notify programs running in the window whenever it is resized.

The VT102 and Tektronix 4014 terminals all have their own windows so that you can edit text in one and look at graphics in the other at the same time. To maintain the correct aspect ratio (height/width), Tektronix graphics will be restricted to the largest box with a 4014's aspect ratio that will fit in the window. This box is located in the upper-left area of the window.

Although both windows may be displayed at the same time, one of them is considered the active window for receiving keyboard input and terminal output. This is the window that contains the text cursor. The active window can be chosen through escape sequences, the VT Options menu in the VT102 window, and the Tek Options menu in the 4014 window.

EMULATIONS

The VT102 emulation is fairly complete, but does not support smooth scrolling, VT52 mode, the blinking character attribute nor the double-wide and double-size character sets. `termcap(5)` entries that work with `xterm` include `xterm`, `vt102`, `vt100`, and `ansi`, and `xterm` automatically searches the `termcap` file in this order for these entries and then sets the `TERM` and the `TERMCAP` environment variables.

Many of the special `xterm` features may be modified under program control through a set of escape sequences different from the standard VT102 escape sequences. (See the "Xterm Control Sequences" document.)

The Tektronix 4014 emulation is also fairly good. It supports 12-bit graphics addressing, scaled to the window size. Four different font sizes and five different lines types are supported. There is no write-through or defocused mode support. The Tektronix text and graphics commands are recorded internally by `xterm` and may be written to a file by sending the `COPY` escape sequence (or through the Tektronix menu, discussed later in this section). The name of the file will be `COPYyy-MM-dd.hh:mm:ss`, where *yy*, *MM*, *dd*, *hh*, *mm*, and *ss* are the year, month, day, hour, minute, and second when the `COPY` was performed (the file is created in the directory `xterm` is started in, or the home directory for a login `xterm`).

OTHER FEATURES

`xterm` automatically highlights the text cursor when the pointer enters the window (selected) and unhighlights it when the pointer leaves the window (unselected). If the window is the focus window, then the text cursor is highlighted no matter where the pointer is. In VT102 mode, there are escape sequences to activate and deactivate an alternate screen buffer, which

is the same size as the display area of the window. When activated, the current screen is saved and replaced with the alternate screen. Saving of lines scrolled off the top of the window is disabled until the normal screen is restored. The `termcap(5)` entry for `xterm` allows the visual editor `vi(1)` to switch to the alternate screen for editing and to restore the screen on exit.

In either VT102 or Tektronix mode, there are escape sequences to change the name of the windows. See `xterm Control Sequences` for details.

OPTIONS

The `xterm` terminal emulator accepts all of the standard X Toolkit command-line options as well as the following (if the option begins with a + instead of a -, the option is restored to its default value):

<code>-help</code>	This causes <code>xterm</code> to print out a verbose message describing its options.
<code>-132</code>	Normally, the VT102 <code>DECCOLM</code> escape sequence that switches between 80 and 132 column mode is ignored. This option causes the <code>DECCOLM</code> escape sequence to be recognized, and the <code>xterm</code> window will resize appropriately.
<code>-ah</code>	This option indicates that <code>xterm</code> should always highlight the text cursor. By default, <code>xterm</code> will display a hollow text cursor whenever the focus is lost or the pointer leaves the window.
<code>ah</code>	This option indicates that <code>xterm</code> should do text cursor highlighting based on focus.
<code>-b number</code>	This option specifies the size of the inner border (the distance between the outer edge of the characters and the window border) in pixels. The default is 2.
<code>-cb</code>	Set the vt100 resource <code>cutToBeginningOfLine</code> to <code>False</code> .
<code>cb</code>	Set the vt100 resource <code>cutToBeginningOfLine</code> to <code>True</code> .
<code>-cc characterclassrange: value[,...]</code>	This sets classes indicated by the given ranges to use in selecting by words. See the subsection "Character Classes."
<code>-cn</code>	This option indicates that newlines should not be cut in line-mode selections.
<code>cn</code>	This option indicates that newlines should be cut in line-mode selections.
<code>-cr color</code>	This option specifies the color to use for text cursor. The default is to use the same foreground color that is used for text.
<code>-cu</code>	This option indicates that <code>xterm</code> should work around a bug in the <code>more(1)</code> program that causes it to incorrectly display lines that are exactly the width of the window and are followed by a line beginning with a tab (the leading tabs are not displayed). This option is so named because it was originally thought to be a bug in the <code>curses(3x)</code> cursor motion package.
<code>cu</code>	This option indicates that <code>xterm</code> should not work around the <code>more(3x)</code> bug mentioned in the preceding paragraph.
<code>-e program [arguments . . .]</code>	This option specifies the program (and its command-line arguments) to be run in the <code>xterm</code> window. It also sets the window title and icon name to be the basename of the program being executed if neither <code>-T</code> nor <code>-n</code> are given on the command line. This must be the last option on the command line.
<code>-fb font</code>	This option specifies a font to be used when displaying bold text. This font must be the same height and width as the normal font. If only one of the normal or bold fonts is

	specified, it will be used as the normal font and the bold font will be produced by overstriking this font. The default is to do overstriking of the normal font.
-im	Turn on the <code>useInsertMode</code> resource.
+im	Turn off the <code>useInsertMode</code> resource.
-j	This option indicates that <code>xterm</code> should do jump scrolling. Normally, text is scrolled one line at a time; this option allows <code>xterm</code> to move multiple lines at a time so that it doesn't fall as far behind. Its use is strongly recommended because it makes <code>xterm</code> much faster when scanning through large amounts of text. The VT100 escape sequences for enabling and disabling smooth scroll as well as the VT Options menu can be used to turn this feature on or off.
j	This option indicates that <code>xterm</code> should not do jump scrolling.
-ls	This option indicates that the shell that is started in the <code>xterm</code> window will be a login shell (that is, the first character of <code>argv[0]</code> will be a dash, indicating to the shell that it should read the user's <code>.login</code> or <code>.profile</code>).
ls	This option indicates that the shell that is started should not be a login shell (that is, it will be a normal subshell).
-mb	This option indicates that <code>xterm</code> should ring a margin bell when the user types near the right end of a line. This option can be turned on and off from the VT Options menu.
mb	This option indicates that margin bell should not be rung.
-mcmi i seconds	This option specifies the maximum time between multiclick selections.
-ms color	This option specifies the color to be used for the pointer cursor. The default is to use the foreground color.
-nb number	This option specifies the number of characters from the right end of a line at which the margin bell, if enabled, will ring. The default is 10.
-rw	This option indicates that reverse-wraparound should be allowed. This allows the cursor to back up from the leftmost column of one line to the rightmost column of the previous line. This is very useful for editing long shell command lines and is encouraged. This option can be turned on and off from the VT Options menu.
rw	This option indicates that reverse-wraparound should not be allowed.
-aw	This option indicates that auto-wraparound should be allowed. This allows the cursor to automatically wrap to the beginning of the next line when it is at the rightmost position of a line and text is output.
aw	This option indicates that auto-wraparound should not be allowed.
-s	This option indicates that <code>xterm</code> may scroll asynchronously, meaning that the screen does not have to be kept completely up to date while scrolling. This allows <code>xterm</code> to run faster when network latencies are very high and is typically useful when running across a very large Internet or many gateways.

s	This option indicates that <code>xterm</code> should scroll synchronously.
-sb	This option indicates that some number of lines that are scrolled off the top of the window should be saved and that a scrollbar should be displayed so that those lines can be viewed. This option may be turned on and off from the VT Options menu.
sb	This option indicates that a scrollbar should not be displayed.
-sf	This option indicates that Sun Function Key escape codes should be generated for function keys.
sf	This option indicates that the standard escape codes should be generated for function keys.
-si	This option indicates that output to a window should not automatically reposition the screen to the bottom of the scrolling region. This option can be turned on and off from the VT Options menu.
si	This option indicates that output to a window should cause it to scroll to the bottom.
-sk	This option indicates that pressing a key while using the scrollbar to review previous lines of text should cause the window to be repositioned automatically in the normal position at the bottom of the scroll region.
sk	This option indicates that pressing a key while using the scrollbar should not cause the window to be repositioned.
-sl number	This option specifies the number of lines to save that have been scrolled off the top of the screen. The default is 64.
-t	This option indicates that <code>xterm</code> should start in Tektronix mode, rather than in VT102 mode. Switching between the two windows is done using the Options menus.
t	This option indicates that <code>xterm</code> should start in VT102 mode.
-tm string	This option specifies a series of terminal setting keywords followed by the characters that should be bound to those functions, similar to the <code>stty</code> program. Allowable keywords include: <code>intr</code> , <code>quit</code> , <code>erase</code> , <code>kill</code> , <code>eof</code> , <code>eol</code> , <code>swtch</code> , <code>start</code> , <code>stop</code> , <code>brk</code> , <code>susp</code> , <code>dsusp</code> , <code>rprnt</code> , <code>flush</code> , <code>weras</code> , and <code>lnext</code> . Control characters may be specified as <code>^char</code> (for example, <code>^c</code> or <code>^u</code>) and <code>^?</code> may be used to indicate delete.
-tn name	This option specifies the name of the terminal type to be set in the <code>TERM</code> environment variable. This terminal type must exist in the <code>termcap(5)</code> database and should have <code>li#</code> and <code>co#</code> entries.
-ut	This option indicates that <code>xterm</code> shouldn't write a record into the system log file <code>/etc/utmp</code> .
ut	This option indicates that <code>xterm</code> should write a record into the system log file <code>/etc/utmp</code> .
-vb	This option indicates that a visual bell is preferred over an audible one. Instead of ringing the terminal bell whenever a <code>Ctrl+G</code> is received, the window will be flashed.
vb	This option indicates that a visual bell should not be used.
-wf	This option indicates that <code>xterm</code> should wait for the window to be mapped the first time before starting the subprocess so that the initial terminal size settings and environment variables are

	correct. It is the application's responsibility to catch subsequent terminal size changes.
wf	This option indicates that <code>xterm</code> should not wait before starting the subprocess.
-C	This option indicates that this window should receive console output. This is not supported on all systems. To obtain console output, you must be the owner of the console device, and you must have read and write permission for it. If you are running <code>x</code> under <code>xdm</code> on the console screen, you may need to have the session startup and reset programs explicitly change the ownership of the console device in order to get this option to work.
-Sccn	This option specifies the last two letters of the name of a pseudo-terminal to use in slave mode, plus the number of the inherited file descriptor. The option is parsed <code>"%c%c%d"</code> . This allows <code>xterm</code> to be used as an input and output channel for an existing program and is sometimes used in specialized applications.

The following command-line arguments are provided for compatibility with older versions. They may not be supported in the next release as the X Toolkit provides standard options that accomplish the same task.

%geom	This option specifies the preferred size and position of the Tektronix window. It is shorthand for specifying the <code>*tekGeometry</code> resource.
geom	This option specifies the preferred position of the icon window. It is shorthand for specifying the <code>*iconGeometry</code> resource.
-T string	This option specifies the title for <code>xterm</code> 's windows. It is equivalent to <code>-title</code> .
-n string	This option specifies the icon name for <code>xterm</code> 's windows. It is shorthand for specifying the <code>*iconName</code> resource. Note that this is not the same as the toolkit option <code>-name</code> (see below). The default icon name is the application name.
-r	This option indicates that reverse video should be simulated by swapping the foreground and background colors. It is equivalent to <code>-rv</code> .
-w number	This option specifies the width in pixels of the border surrounding the window. It is equivalent to <code>-borderwidth</code> or <code>-bw</code> .

The following standard X Toolkit command-line arguments are commonly used with `xterm`:

-bg color	This option specifies the color to use for the background of the window. The default is <code>white</code> .
-bd color	This option specifies the color to use for the border of the window. The default is <code>black</code> .
-bw number	This option specifies the width in pixels of the border surrounding the window.
-fg color	This option specifies the color to use for displaying text. The default is <code>black</code> .
-fn font	This option specifies the font to be used for displaying normal text. The default is <code>fixed</code> .

<code>-name name</code>	This option specifies the application name under which resources are to be obtained, rather than the default executable filename. Name should not contain <code>.</code> or <code>*</code> characters.
<code>-title string</code>	This option specifies the window title string, which may be displayed by window managers if the user so chooses. The default title is the command line specified after the <code>-e</code> option, if any; otherwise, the application name.
<code>-rv</code>	This option indicates that reverse video should be simulated by swapping the foreground and background colors.
<code>-geometry geometry</code>	This option specifies the preferred size and position of the VT102 window; see <code>x(1)</code> .
<code>-display display</code>	This option specifies the X server to contact; see <code>x(1)</code> .
<code>-xrm resourcestring</code>	This option specifies a resource string to be used. This is especially useful for setting resources that do not have separate command-line options.
<code>-iconic</code>	This option indicates that <code>xterm</code> should ask the window manager to start it as an icon rather than as the normal window.

RESOURCES

The program understands all of the core X Toolkit resource names and classes as well as the following:

<code>iconGeometry</code> (class <code>IconGeometry</code>)	Specifies the preferred size and position of the application when iconified. It is not necessarily obeyed by all window managers.
<code>iconName</code> (class <code>IconName</code>)	Specifies the icon name. The default is the application name.
<code>termName</code> (class <code>TermName</code>)	Specifies the terminal type name to be set in the <code>TERM</code> environment variable.
<code>title</code> (class <code>Title</code>)	Specifies a string that may be used by the window manager when displaying this application.
<code>ttyModes</code> (class <code>TtyModes</code>)	Specifies a string containing terminal setting keywords and the characters to which they may be bound. Allowable keywords include <code>intr</code> , <code>quit</code> , <code>erase</code> , <code>kill</code> , <code>eof</code> , <code>eol</code> , <code>swtch</code> , <code>start</code> , <code>stop</code> , <code>brk</code> , <code>susp</code> , <code>dsusp</code> , <code>rprnt</code> , <code>flush</code> , <code>weras</code> , and <code>lnext</code> . Control characters may be specified as <code>^char</code> (for example, <code>^c</code> or <code>^u</code>) and <code>^?</code> may be used to indicate delete. This is very useful for overriding the default terminal settings without having to do an <code>stty</code> every time an <code>xterm</code> is started.
<code>useInsertMode</code> (class <code>UseInsertMode</code>)	Force use of insert mode by adding appropriate entries to the <code>TERMCAP</code> environment variable. This is useful if the system <code>termcap</code> is broken. The default is <code>False</code> .
<code>utmpInhibit</code> (class <code>UtmpInhibit</code>)	Specifies whether or not <code>xterm</code> should try to record the user's terminal in <code>/etc/utmp</code> .
<code>sunFunctionKeys</code> (class <code>SunFunctionKeys</code>)	Specifies whether or not Sun Function Key escape codes should be generated for function keys instead of standard escape sequences.
<code>waitForMap</code> (class <code>WaitForMap</code>)	Specifies whether or not <code>xterm</code> should wait for the initial window map before starting the subprocess. The default is <code>false</code> .

The following resources are specified as part of the vt100 widget (class `VT100`):

<code>allowSendEvents</code> (class <code>AllowSendEvents</code>)	Specifies whether or not synthetic key and button events (generated using the X protocol <code>SendEvent</code> request) should be interpreted or discarded. The default is <code>False</code> , meaning they are discarded. Note that allowing such events creates a very large security hole.
<code>alwaysHighlight</code> (class <code>AlwaysHighlight</code>)	Specifies whether or not <code>xterm</code> should always display a highlighted text cursor. By default, a hollow text cursor is displayed whenever the pointer moves out of the window or the window loses the input focus.
<code>appcursorDefault</code> (class <code>AppcursorDefault</code>)	If <code>true</code> , the cursor keys are initially in application mode. The default is <code>false</code> .
<code>appkeypadDefault</code> (class <code>AppkeypadDefault</code>)	If <code>true</code> , the keypad keys are initially in application mode. The default is <code>false</code> .
<code>autoWrap</code> (class <code>AutoWrap</code>)	Specifies whether or not auto-wraparound should be enabled. The default is <code>true</code> .
<code>bellSuppressTime</code> (class <code>BellSuppressTime</code>)	Number of milliseconds after a bell command is sent during which additional bells will be suppressed. Default is <code>200</code> . If set non-zero, additional bells will also be suppressed until the server reports that processing of the first bell has been completed; this feature is most useful with the visible bell.
<code>boldFont</code> (class <code>BoldFont</code>)	Specifies the name of the bold font to use instead of overstriking.
<code>c132</code> (class <code>C132</code>)	Specifies whether or not the VT102 <code>DECCOLM</code> escape sequence should be honored. The default is <code>false</code> .
<code>cutNewline</code> (class <code>CutNewline</code>)	If <code>false</code> , triple-clicking to select a line does not include the <code>Newline</code> at the end of the line. If <code>true</code> , the <code>Newline</code> is selected. The default is <code>true</code> .
<code>cutToBeginningOfLine</code> (class <code>CutToBeginningOfLine</code>)	If <code>false</code> , triple-clicking to select a line selects only from the current word forward. If <code>true</code> , the entire line is selected. The default is <code>true</code> .
<code>charClass</code> (class <code>CharClass</code>)	Specifies comma-separated lists of character class bindings of the form <code>[low-high:value]</code> . These are used in determining which sets of characters should be treated the same when doing cut and paste. See the section on specifying character classes.
<code>curses</code> (class <code>Curses</code>)	Specifies whether or not the last column bug in <code>more(1)</code> should be worked around. See the <code>-cu</code> option for details. The default is <code>false</code> .
<code>background</code> (class <code>Background</code>)	Specifies the color to use for the background of the window. The default is <code>white</code> .
<code>foreground</code> (class <code>Foreground</code>)	Specifies the color to use for displaying text in the window. Setting the class name instead of the instance name is an easy way to have everything that would normally appear in the text color change color. The default is <code>black</code> .
<code>cursorColor</code> (class <code>Foreground</code>)	Specifies the color to use for the text cursor. The default is <code>black</code> .
<code>eightBitInput</code> (class <code>EightBitInput</code>)	If <code>true</code> , metacharacters input from the keyboard are presented as a single character with the eighth bit turned on. If <code>false</code> , metacharacters are converted into a two-character sequence with the character itself preceded by <code>ESC</code> . The default is <code>true</code> .

<code>eightBitOutput</code> (class <code>EightBitOutput</code>)	Specifies whether or not eight-bit characters sent from the host should be accepted as is or stripped when printed. The default is <code>true</code> .
<code>font</code> (class <code>Font</code>)	Specifies the name of the normal font. The default is <code>fixed</code> .
<code>font1</code> (class <code>Font1</code>)	Specifies the name of the first alternative font.
<code>font2</code> (class <code>Font2</code>)	Specifies the name of the second alternative font.
<code>font3</code> (class <code>Font3</code>)	Specifies the name of the third alternative font.
<code>font4</code> (class <code>Font4</code>)	Specifies the name of the fourth alternative font.
<code>font5</code> (class <code>Font5</code>)	Specifies the name of the fifth alternative font.
<code>font6</code> (class <code>Font6</code>)	Specifies the name of the sixth alternative font.
<code>geometry</code> (class <code>Geometry</code>)	Specifies the preferred size and position of the VT102 window.
<code>hpLowerLeftBugCompat</code> (class <code>HpLowerLeftBugCompat</code>)	Specifies whether to work around a bug in HP's <code>xdm</code> , which ignores <code>termcap</code> and always sends ESC F to move to the lower-left corner. <code>true</code> causes <code>xterm</code> to interpret ESC F as a request to move to the lower-left corner of the screen. The default is <code>false</code> .
<code>internalBorder</code> (class <code>BorderWidth</code>)	Specifies the number of pixels between the characters and the window border. The default is 2.
<code>jumpScroll</code> (class <code>JumpScroll</code>)	Specifies whether or not jump scroll should be used. The default is <code>true</code> .
<code>loginShell</code> (class <code>LoginShell</code>)	Specifies whether or not the shell to be run in the window should be started as a login shell. The default is <code>false</code> .
<code>marginBell</code> (class <code>MarginBell</code>)	Specifies whether or not the bell should be rung when the user types near the right margin. The default is <code>false</code> .
<code>multiClickTime</code> (class <code>MultiClickTime</code>)	Specifies the maximum time in milliseconds between multiclick select events. The default is 250 milliseconds.
<code>multiScroll</code> (class <code>MultiScroll</code>)	Specifies whether or not scrolling should be done asynchronously. The default is <code>false</code> .
<code>nMarginBell</code> (class <code>Column</code>)	Specifies the number of characters from the right margin at which the margin bell should be rung, when enabled.
<code>pointerColor</code> (class <code>Foreground</code>)	Specifies the foreground color of the pointer. The default is <code>XtDefaultForeground</code> .
<code>pointerColorBackground</code> (class <code>Background</code>)	Specifies the background color of the pointer. The default is <code>XtDefaultBackground</code> .
<code>pointerShape</code> (class <code>Cursor</code>)	Specifies the name of the shape of the pointer. The default is <code>xterm</code> .
<code>resizeGravity</code> (class <code>ResizeGravity</code>)	Affects the behavior when the window is resized to be taller or shorter. <code>NorthWest</code> specifies that the top line of text on the screen stay fixed. If the window is made shorter, lines are dropped from the bottom; if the window is made taller, blank lines are added at the bottom. This is compatible with the behavior in R4. <code>SouthWest</code> (the default) specifies that the bottom line of text on the screen stay fixed. If the window is made taller, additional saved lines will be scrolled down onto the screen; if the window is made shorter, lines will be scrolled off the top of the screen, and the top saved lines will be dropped.
<code>reverseVideo</code> (class <code>ReverseVideo</code>)	Specifies whether <code>reverse video</code> should be simulated. The default is <code>false</code> .

```
reverseWrap
(class ReverseWrap)

saveLines
(class SaveLines)

scrollBar
(class ScrollBar)

scrollTTYOutput
(class ScrollCond)

scrollKey
(class ScrollCond)

scrollLines
(class ScrollLines)

signalInhibit
(class SignalInhibit)

tekGeometry
(class Geometry)

tekInhibit
(class TekInhibit)

tekSmall (class TekSmall)

tekStartup
(class TekStartup)

titeInhibit
(class TiteInhibit)

translations
(class Translations)

visualBell
(class VisualBell)
```

The following resources are specified as part of the `tek4014` widget (class `Tek4014`):

```
width (class Width)
height (class Height)
fontLarge (class Font)
font2 (class Font)
font3 (class Font)
fontSmall (class Font)
initialFont (class InitialFont)
```

Specifies whether or not `reverse-wraparound` should be enabled. The default is `false`.

Specifies the number of lines to save beyond the top of the screen when a scrollbar is turned on. The default is 64.

Specifies whether or not the scrollbar should be displayed. The default is `false`.

Specifies whether or not output to the terminal should automatically cause the scrollbar to go to the bottom of the scrolling region. The default is `true`.

Specifies whether or not pressing a key should automatically cause the scrollbar to go to the bottom of the scrolling region. The default is `false`.

Specifies the number of lines that the `scroll-back` and `scroll-forward` actions should use as a default. The default value is 1.

Specifies whether or not the entries in the Main Options menu for sending signals to `xterm` should be disallowed. The default is `false`.

Specifies the preferred size and position of the Tektronix window.

Specifies whether or not the escape sequence to enter Tektronix mode should be ignored. The default is `false`.

Specifies whether or not the Tektronix mode window should start in its smallest size if no explicit geometry is given. This is useful when running `xterm` on displays with small screens. The default is `false`.

Specifies whether or not `xterm` should start up in Tektronix mode. The default is `false`.

Specifies whether or not `xterm` should remove `ti` and `termcap` entries (used to switch between alternate screens on startup of many screen-oriented programs) from the `TERMCAP` string. If set, `xterm` also ignores the escape sequence to switch to the alternate screen.

Specifies the key and button bindings for menus, selections, “programmed strings,” and so on. See the “ACTIONS” subsection, later in this section.

Specifies whether or not a visible bell (that is, flashing) should be used instead of an audible bell when Control-G is received. The default is `false`.

Specifies the width of the Tektronix window in pixels.

Specifies the height of the Tektronix window in pixels.

Specifies the large font to use in the Tektronix window.

Specifies font number 2 to use in the Tektronix window.

Specifies font number 3 to use in the Tektronix window.

Specifies the small font to use in the Tektronix window.

Specifies which of the four Tektronix fonts to use initially.

Values are the same as for the `set-tek-text` action. The default is `large`.

ginTerminator
(class GinTerminator)

Specifies what character(s) should follow a GIN report or status report. The possibilities are `none`, which sends no terminating characters, `CRonly`, which sends `CR`, and `CR&EOT`, which sends both `CR` and `EOT`. The default is `none`.

The resources that may be specified for the various menus are described in the documentation for the Athena `SimpleMenu` widget. The name and classes of the entries in each of the menus are listed next.

The `mainMenu` has the following entries:

`securekbd` (class `SmeBSB`)
`allowsends` (class `SmeBSB`)
`redraw` (class `SmeBSB`)
`line1` (class `SmeLine`)
`suspend` (class `SmeBSB`)

This entry invokes the `secure()` action.

This entry invokes the `allow-send-events(toggle)` action.

This entry invokes the `redraw()` action.

This is a separator.

This entry invokes the `send-signal(tstp)` action on systems that support job control.

This entry invokes the `send-signal(cont)` action on systems that support job control.

This entry invokes the `send-signal(int)` action.

This entry invokes the `send-signal(hup)` action.

This entry invokes the `send-signal(term)` action.

This entry invokes the `send-signal(kill)` action.

This is a separator.

This entry invokes the `quit()` action.

`continue` (class `SmeBSB`)

`interrupt` (class `SmeBSB`)

`hangup` (class `SmeBSB`)

`terminate` (class `SmeBSB`)

`kill` (class `SmeBSB`)

`line2` (class `SmeLine`)

`quit` (class `SmeBSB`)

The `vtMenu` has the following entries:

`scrollbar` (class `SmeBSB`)
`jumpscroll` (class `SmeBSB`)
`reversevideo` (class `SmeBSB`)
`autowrap` (class `SmeBSB`)
`reversewrap` (class `SmeBSB`)
`autolinefeed` (class `SmeBSB`)
`appcursor` (class `SmeBSB`)
`appkeypad` (class `SmeBSB`)
`scrollkey` (class `SmeBSB`)
`scrollttyoutput`
(class `SmeBSB`)
`allow132` (class `SmeBSB`)
`cursesemul` (class `SmeBSB`)
`visualbell` (class `SmeBSB`)
`marginbell` (class `SmeBSB`)
`altscreen` (class `SmeBSB`)
`line1` (class `SmeLine`)
`softreset` (class `SmeBSB`)
`hardreset` (class `SmeBSB`)
`clearsavedlines` (class `SmeBSB`)"
`line2` (class `SmeLine`)
`tekshow` (class `SmeBSB`)
`tekmode` (class `SmeBSB`)

This entry invokes the `set-scrollbar(toggle)` action.

This entry invokes the `set-jumpscroll(toggle)` action.

This entry invokes the `set-reverse-video(toggle)` action.

This entry invokes the `set-autowrap(toggle)` action.

This entry invokes the `set-reversewrap(toggle)` action.

This entry invokes the `set-autolinefeed(toggle)` action.

This entry invokes the `set-appcursor(toggle)` action.

This entry invokes the `set-appkeypad(toggle)` action.

This entry invokes the `set-scroll-on-key(toggle)` action.

This entry invokes the `set-scroll-on-tty-output(toggle)` action.

This entry invokes the `set-allow132(toggle)` action.

This entry invokes the `set-cursesemul(toggle)` action.

This entry invokes the `set-visualbell(toggle)` action.

This entry invokes the `set-marginbell(toggle)` action.

This entry is currently disabled.

This is a separator.

This entry invokes the `soft-reset()` action.

This entry invokes the `hard-reset()` action.

This entry invokes the `clear-saved-lines()` action.

This is a separator.

This entry invokes the `set-visibility(tek,toggle)` action.

This entry invokes the `set-terminal-type(tek)` action.

`vthide` (class `SmeBSB`)

This entry invokes the `set-visibility(vt,off)` action.

The `fontMenu` has the following entries:

`fontdefault` (class `SmeBSB`)

This entry invokes the `set-vt-font(d)` action.

`font1` (class `SmeBSB`)

This entry invokes the `set-vt-font(1)` action.

`font2` (class `SmeBSB`)

This entry invokes the `set-vt-font(2)` action.

`font3` (class `SmeBSB`)

This entry invokes the `set-vt-font(3)` action.

`font4` (class `SmeBSB`)

This entry invokes the `set-vt-font(4)` action.

`font5` (class `SmeBSB`)

This entry invokes the `set-vt-font(5)` action.

`font6` (class `SmeBSB`)

This entry invokes the `set-vt-font(6)` action.

`fontescape` (class `SmeBSB`)

This entry invokes the `set-vt-font(e)` action.

`fontsel` (class `SmeBSB`)

This entry invokes the `set-vt-font(s)` action.

The `tekMenu` has the following entries:

`tektextlarge` (class `SmeBSB`)

This entry invokes the `set-tek-text(1)` action.

`tektext2` (class `SmeBSB`)

This entry invokes the `set-tek-text(2)` action.

`tektext3` (class `SmeBSB`)

This entry invokes the `set-tek-text(3)` action.

`tektextsmall` (class `SmeBSB`)

This entry invokes the `set-tek-text(s)` action.

`line1` (class `SmeLine`)

This is a separator.

`tekpage` (class `SmeBSB`)

This entry invokes the `tek-page()` action.

`tekreset` (class `SmeBSB`)

This entry invokes the `tek-reset()` action.

`tekcopy` (class `SmeBSB`)

This entry invokes the `tek-copy()` action.

`line2` (class `SmeLine`)

This is a separator.

`vtshow` (class `SmeBSB`)

This entry invokes the `set-visibility(vt,toggle)` action.

`vtmode` (class `SmeBSB`)

This entry invokes the `set-terminal-type(vt)` action.

`tekhide` (class `SmeBSB`)

This entry invokes the `set-visibility(tek,toggle)` action.

The following resources are useful when specified for the Athena Scrollbar widget:

`thickness` (class `Thickness`)

Specifies the width in pixels of the scrollbar.

`background` (class `Background`)

Specifies the color to use for the background of the scrollbar.

`foreground` (class `Foreground`)

Specifies the color to use for the foreground of the scrollbar.

The “thumb” of the scrollbar is a simple checkerboard pattern alternating pixels for foreground and background color.

POINTER USAGE

Once the VT102 window is created, `xterm` allows you to select text and copy it within the same or other windows.

The selection functions are invoked when the pointer buttons are used with no modifiers, and when they are used with the Shift key. The assignment of the functions described in this subsection to keys and buttons may be changed through the resource database; see the “Actions” subsection later in this section.

Pointer button one (usually left) is used to save text into the cut buffer. Move the cursor to the beginning of the text, and then hold the button down while moving the cursor to the end of the region and releasing the button. The selected text is highlighted and is saved in the global cut buffer and made the PRIMARY selection when the button is released. Double-clicking selects by words. Triple-clicking selects by lines. Quadruple-clicking goes back to characters, and so on. Multiple-click is determined by the time from button up to button down, so you can change the selection unit in the middle of a selection. If the key/button bindings specify that an X selection is to be made, `xterm` will leave the selected text highlighted for as long as it is the selection owner.

Pointer button two (usually middle) “types” (pastes) the text from the PRIMARY selection, if any, otherwise from the cut buffer, inserting it as keyboard input.

Pointer button three (usually right) extends the current selection. (Without loss of generality, you can swap “right” and “left” everywhere in the rest of this paragraph.) If pressed while closer to the right edge of the selection than the left, it extends/contracts the right edge of the selection. If you contract the selection past the left edge of the selection, xterm assumes you really meant the left edge, restores the original selection, then extends/contracts the left edge of the selection. Extension starts in the selection unit mode that the last selection or extension was performed in; you can multiple-click to cycle through them.

By cutting and pasting pieces of text without trailing new lines, you can take text from several places in different windows and form a command to the shell, for example, or take output from a program and insert it into your favorite editor. Since the cut buffer is globally shared among different applications, you should regard it as a file whose contents you know. The terminal emulator and other text programs should be treating it as if it were a text file; that is, the text is delimited by new lines.

The scroll region displays the position and amount of text currently showing in the window (highlighted) relative to the amount of text actually saved. As more text is saved (up to the maximum), the size of the highlighted area decreases.

Clicking button one with the pointer in the scroll region moves the adjacent line to the top of the display window.

Clicking button three moves the top line of the display window down to the pointer position.

Clicking button two moves the display to a position in the saved text that corresponds to the pointer’s position in the scrollbar.

Unlike the VT102 window, the Tektronix window does not allow the copying of text. It does allow Tektronix GIN mode, and in this mode the cursor will change from an arrow to a cross. Pressing any key will send that key and the current coordinate of the cross cursor. Pressing button one, two, or three will return the letters `l`, `m`, and `r`, respectively. If the Shift key is pressed when a pointer button is pressed, the corresponding uppercase letter is sent. To distinguish a pointer button from a key, the high bit of the character is set (but this bit is normally stripped unless the terminal mode is RAW; see `tty(4)` for details).

MENUS

xterm has four menus: `mainMenu`, `vtMenu`, `fontMenu`, and `tekMenu`. Each menu pops up under the correct combinations of key and button presses. Most menus are divided into two sections, separated by a horizontal line. The top portion contains various modes that can be altered. A check mark appears next to a mode that is currently active. Selecting one of these modes toggles its state. The bottom portion of the menu consists of command entries; selecting one of these performs the indicated function.

The `xterm` menu pops up when the Control key and pointer button one are pressed in a window. The `mainMenu` contains items that apply to both the VT102 and Tektronix windows. The Secure Keyboard mode is used when typing in passwords or other sensitive data in an unsecured environment. (See the “SECURITY” subsection.) Notable entries in the command section of the menu are the Continue, Suspend, Interrupt, Hangup, Terminate, and Kill, which send the `SIGCONT`, `SIGTSTP`, `SIGINT`, `SIGHUP`, `SIGTERM`, and `SIGKILL` signals, respectively, to the process group of the process running under xterm (usually the shell). The Continue function is especially useful if the user has accidentally typed CTRL-Z, suspending the process.

The `vtMenu` sets various modes in the VT102 emulation, and is popped up when the Control key and pointer button two are pressed in the VT102 window. In the command section of this menu, the Soft Reset entry will reset scroll regions. This can be convenient when some program has left the scroll regions set incorrectly (often a problem when using VMS or TOPS-20). The Full Reset entry will clear the screen, reset tabs to every eight columns, and reset the terminal modes (such as wrap and smooth scroll) to their initial states just after xterm has finished processing the command-line options.

The `fontMenu` sets the font used in the VT102 window. In addition to the default font and a number of alternatives that are set with resources, the menu offers the font last specified by the Set Font escape sequence (see the document “Xterm Control Sequences”) and the current selection as a font name (if the PRIMARY selection is owned).

The `tekMenu` sets various modes in the Tektronix emulation, and is popped up when the Control key and pointer button two are pressed in the Tektronix window. The current font size is checked in the Modes section of the menu. The `PAGE` entry in the Command section clears the Tektronix window.

SECURITY

X environments differ in their security consciousness. Most servers, run under `xdm`, are capable of using a “magic cookie” authorization scheme that can provide a reasonable level of security for many people. If your server is only using a host-based mechanism to control access to the server (see `xhost(1)`), then if you enable access for a host and other users are also permitted to run clients on that same host, there is every possibility that someone can run an application that will use the basic services of the `x` protocol to snoop on your activities, potentially capturing a transcript of everything you type at the keyboard. This is of particular concern when you want to type in a password or other sensitive data. The best solution to this problem is to use a better authorization mechanism than host-based control, but a simple mechanism exists for protecting keyboard input in `xterm`.

The `xterm` menu (see “Menus,” earlier in this section) contains a `Secure Keyboard` entry which, when enabled, ensures that all keyboard input is directed only to `xterm` (using the `GrabKeyboard` protocol request). When an application prompts you for a password (or other sensitive data), you can enable `Secure Keyboard` using the menu, type in the data, and then disable `Secure Keyboard` using the menu again. Only one X client at a time can secure the keyboard, so when you attempt to enable `Secure Keyboard`, it may fail. In this case, the bell will sound. If the `Secure Keyboard` succeeds, the foreground and background colors will be exchanged (as if you selected the `Reverse Video` entry in the Modes menu); they will be exchanged again when you exit secure mode. If the colors do not switch, then you should be very suspicious that you are being spoofed. If the application you are running displays a prompt before asking for the password, it is safest to enter secure mode before the prompt gets displayed, and to make sure that the prompt gets displayed correctly (in the new colors), to minimize the probability of spoofing. You can also bring up the menu again and make sure that a check mark appears next to the entry.

`Secure Keyboard` mode will be disabled automatically if your `xterm` window becomes iconified (or otherwise unmapped), or if you start up a reparenting window manager (that places a title bar or other decoration around the window) while in `Secure Keyboard` mode. (This is a feature of the `x` protocol that isn’t easily overcome.) When this happens, the foreground and background colors will be switched back and the bell will sound in warning.

CHARACTER CLASSES

Clicking the middle mouse button twice in rapid succession will cause all characters of the same class (for example, letters, whitespace, punctuation) to be selected. Since different people have different preferences for what should be selected (for example, should filenames be selected as a whole or only the separate subnames?), the default mapping can be overridden through the use of the `charClass` (`class CharClass`) resource.

This resource is a series of comma-separated `range: value` pairs. The range is either a single number or low-high in the range of 0 to 127, corresponding to the ASCII code for the character or characters to be set. The value is arbitrary, although the default table uses the character number of the first character occurring in the set.

The default table is

```
static int charClass[128] = {
/* NUL SOH STX ETX EOT ENQ ACK BEL */
32, 1, 1, 1, 1, 1, 1, 1,
/* BS HT NL VT NP CR SO SI */
1, 32, 1, 1, 1, 1, 1, 1,
/* DLE DC1 DC2 DC3 DC4 NAK SYN ETB */
1, 1, 1, 1, 1, 1, 1, 1,
/* CAN EM SUB ESC FS GS RS US */
1, 1, 1, 1, 1, 1, 1, 1,
/*SP!#$%&'*/
32, 33, 34, 35, 36, 37, 38, 39,
/*()*+,-./*/
40, 41, 42, 43, 44, 45, 46, 47,
/*0 1 2 3 4 5 6 7 */
}
```

```

48, 48, 48, 48, 48, 48, 48, 48,
/*8 9 ;< => ?*/
48, 48, 58, 59, 60, 61, 62, 63,
/*@ABC D E F G*/
64, 48, 48, 48, 48, 48, 48, 48,
/* H I J K L M N O */
48, 48, 48, 48, 48, 48, 48, 48,
/*P QR S T UVW*/
48, 48, 48, 48, 48, 48, 48, 48,
/*XY Z [\]^ */
48, 48, 48, 91, 92, 93, 94, 48,
/*'ab c d e fg */
96, 48, 48, 48, 48, 48, 48, 48,
/*h ijklm n o */
48, 48, 48, 48, 48, 48, 48, 48,
/*p q rs tu v w */
48, 48, 48, 48, 48, 48, 48, 48,
/*x y zf jg` DEL */
48, 48, 48, 123, 124, 125, 126, 1};

```

For example, the string `33:48,37:48,45-47:48,64:48` indicates that the exclamation mark, percent sign, dash, period, slash, and ampersand characters should be treated the same way as characters and numbers. This is useful for cutting and pasting electronic mailing addresses and filenames.

ACTIONS

It is possible to rebind keys (or sequences of keys) to arbitrary strings for input by changing the translations for the `vt100` or `tek4014` widgets. Changing the translations for events other than key and button events is not expected, and will cause unpredictable behavior. The following actions are provided for using within the `vt100` or `tek4014` translations resources:

`bell([percent])`

This action rings the keyboard bell at the specified percentage above or below the base volume.

`ignore()`

This action ignores the event but checks for special pointer position escape sequences.

`insert()`

This action inserts the character or string associated with the key that was pressed.

`insert-seven-bit()`

This action is a synonym for `insert()`.

`insert-eight-bit()`

This action inserts an eight-bit (Meta) version of the character or string associated with the key that was pressed. The exact action depends on the value of the `eightBitInput` resource.

`insert-selection`
(sourcename [, ...])

This action inserts the string found in the selection or cut buffer indicated by `sourcename`. Sources are checked in the order given (case is significant) until one is found. Commonly used selections include `PRIMARY`, `SECONDARY`, and `CLIPBOARD`. Cut buffers are typically named `CUT_BUFFER0` through `CUT_BUFFER7`.

`keymap(name)`

This action dynamically defines a new translation table whose resource name is `name` with the suffix `Keymap` (case is significant). The name `None` restores the original translation table.

`popup-menu(menuname)`

This action displays the specified pop-up menu. Valid names (case is significant) include `mainMenu`, `vtMenu`, `fontMenu`, and `tekMenu`.

`secure()`

This action toggles the Secure Keyboard mode described in the “Security” subsection, and is invoked from the `securekbd` entry in `mainMenu`.

`select-start()`

This action begins text selection at the current pointer location. See the subsection on “Pointer Usage” for information on making selections.

`select-extend()`

This action tracks the pointer and extends the selection. It should only be bound to Motion events.

`select-end`
(*destname* [, ...])

This action puts the currently selected text into all of the selections or cut buffers specified by *destname*.

`select-cursor-start()`

This action is similar to `select-start` except that it begins the selection at the current text cursor position.

`select-cursor-end`
(*destname* [, ...])

This action is similar to `select-end` except that it should be used with `select-cursor-start`.

`set-vt-font`
(*d*/*1*/*2*/*3*/*4*/*5*/*6*/*e*/*s*
[, *normal font* [, *bold font*]])

This action sets the font or fonts currently being used in the VT102 window. The first argument is a single character that specifies the font to be used: *d* or *D* indicate the default font (the font initially used when *xterm* was started), *1* through *6* indicate the fonts specified by the *font1* through *font6* resources, *e* or *E* indicate the normal and bold fonts that have been set through escape codes (or specified as the second and third action arguments, respectively), and *s* or *S* indicate the font selection (as made by programs such as *xfontsel*(1)) indicated by the second action argument.

`start-extend()`

This action is similar to `select-start` except that the selection is extended to the current pointer location.

`start-cursor-extend()`

This action is similar to `select-extend` except that the selection is extended to the current text cursor position.

`string(string)`

This action inserts the specified text string as if it had been typed. Quotation is necessary if the string contains whitespace or nonalphanumeric characters. If the string argument begins with the characters `0x`, it is interpreted as a hex character constant.

`scroll-back(count [,units])`

This action scrolls the text window backward so that text that had previously scrolled off the top of the screen is now visible. The count argument indicates the number of units (which may be page, half page, pixel, or line) by which to scroll.

`scroll-forw(count [,uni ts])`

This action scroll is similar to `scroll-back` except that it scrolls the other direction.

`allow-send-events`
(*on/off/toggl e*)

This action set or toggles the `allowSendEvents` resource and is also invoked by the `allowsends` entry in `mainMenu`.

`redraw()`

This action redraws the window and is also invoked by the `redraw` entry in `mainMenu`.

`send-signal(si gname)`

This action sends the signal named by *si gname* to the *xterm* subprocess (the shell or program specified with the `-e` command-line option) and is also invoked by the `suspend`, `continue`, `interrupt`, `hangup`, `terminate`, and `kill` entries in `mainMenu`. Allowable signal names are (case is not significant) `tstp` (if supported by the operating system), `suspend` (same as `tstp`), `cont` (if supported by the operating system), `int`, `hup`, `term`, `quit`, `alarm` (same as `alarm`), and `kill`.

`quit()`

This action sends a `SIGHUP` to the subprogram and exits. It is also invoked by the `quit` entry in `mainMenu`.

<code>set-scrollbar(on/off/toggle)</code>	This action toggles the <code>scrollbar</code> resource and is also invoked by the <code>scrollbar</code> entry in <code>vtMenu</code> .
<code>set-jumpscroll(on/off/toggle)</code>	This action toggles the <code>jumpscroll</code> resource and is also invoked by the <code>jumpscroll</code> entry in <code>vtMenu</code> .
<code>set-reverse-video(on/off/toggle)</code>	This action toggles the <code>reverseVideo</code> resource and is also invoked by the <code>reversevideo</code> entry in <code>vtMenu</code> .
<code>set-autowrap(on/off/toggle)</code>	This action toggles automatic wrapping of long lines and is also invoked by the <code>autowrap</code> entry in <code>vtMenu</code> .
<code>set-reversewrap(on/off/toggle)</code>	This action toggles the <code>reverseWrap</code> resource and is also invoked by the <code>reversewrap</code> entry in <code>vtMenu</code> .
<code>set-autolinefeed(on/off/toggle)</code>	This action toggles automatic insertion of line-feeds and is also invoked by the <code>autolinefeed</code> entry in <code>vtMenu</code> .
<code>set-appcursor(on/off/toggle)</code>	This action toggles the handling Application Cursor Key mode and is also invoked by the <code>appcursor</code> entry in <code>vtMenu</code> .
<code>set-appkeypad(on/off/toggle)</code>	This action toggles the handling of Application Key-pad mode and is also invoked by the <code>appkeypad</code> entry in <code>vtMenu</code> .
<code>set-scroll-on-key(on/off/toggle)</code>	This action toggles the <code>scrollKey</code> resource and is also invoked from the <code>scrollkey</code> entry in <code>vtMenu</code> .
<code>set-scroll-on-tty-output(on/off/toggle)</code>	This action toggles the <code>scrollTtyOutput</code> resource and is also invoked from the <code>scrollttyoutput</code> entry in <code>vtMenu</code> .
<code>set-allow132(on/off/toggle)</code>	This action toggles the <code>c132</code> resource and is also invoked from the <code>allow132</code> entry in <code>vtMenu</code> .
<code>set-cursesemul(on/off/toggle)</code>	This action toggles the <code>curses</code> resource and is also invoked from the <code>cursesemul</code> entry in <code>vtMenu</code> .
<code>set-visual-bell(on/off/toggle)</code>	This action toggles the <code>visualBell</code> resource and is also invoked by the <code>visualbell</code> entry in <code>vtMenu</code> .
<code>set-marginbell(on/off/toggle)</code>	This action toggles the <code>marginBell</code> resource and is also invoked from the <code>marginbell</code> entry in <code>vtMenu</code> .
<code>set-altscreen(on/off/toggle)</code>	This action toggles between the alternate and current screens.
<code>soft-reset()</code>	This action resets the scrolling region and is also invoked from the <code>softreset</code> entry in <code>vtMenu</code> .
<code>hard-reset()</code>	This action resets the scrolling region, tabs, window size, and cursor keys, and clears the screen. It is also invoked from the <code>hardreset</code> entry in <code>vtMenu</code> .
<code>clear-saved-lines()</code>	This action does <code>hard-reset()</code> and also clears the history of lines saved off the top of the screen. It is also invoked from the <code>clearsavedlines</code> entry in <code>vtMenu</code> .
<code>set-terminal-type(type)</code>	This action directs output to either the <code>vt</code> or <code>tek</code> windows, according to the <code>type</code> string. It is also invoked by the <code>tekmode</code> entry in <code>vtMenu</code> and the <code>vtmode</code> entry in <code>tekMenu</code> .
<code>set-visibility(vt/tek, on/off/toggle)</code>	This action controls whether or not the <code>vt</code> or <code>tek</code> windows are visible. It is also invoked from the <code>tekshow</code> and <code>vhide</code> entries in <code>vtMenu</code> and the <code>vtshow</code> and <code>tekhide</code> entries in <code>tekMenu</code> .
<code>set-tek-text(large/2/3/small)</code>	This action sets font used in the Tektronix window to the value of the resources <code>tektextrlarge</code> , <code>tektextr2</code> , <code>tektextr3</code> , and <code>tektextrsmall</code> according to the argument. It is also by the entries of the same names as the resources in <code>tekMenu</code> .
<code>tek-page()</code>	This action clears the Tektronix window and is also invoked by the <code>tekpage</code> entry in <code>tekMenu</code> .

tek-reset()

This action resets the Tektronix window and is also invoked by the `tekreset` entry in `tekMenu`.

tek-copy()

This action copies the escape codes used to generate the current window contents to a file in the current directory beginning with the name `COPY`. It is also invoked from the `tekcop` entry in `tekMenu`.

visual-bell()

This action flashes the window quickly.

The Tektronix window also has the following action:

gin-press(l/L/m/M/r/R)

This action sends the indicated graphics input code.

The default bindings in the VT102 window are

```
Shift <KeyPress> Prior: scroll-back(1,halpage) \n\
Shift <KeyPress> Next: scroll-forw(1,halpage) \n\
Shift <KeyPress> Select: select-cursor-start() \
select-cursor-end(PRIMARY, CUT_BUFFER0) \n\
Shift <KeyPress> Insert: insert-selection(PRIMARY, CUT_BUFFER0) \n\
~Meta<KeyPress>: insert-seven-bit() \n\
Meta<KeyPress>: insert-eight-bit() \n\
!Ctrl <Btn1Down>: popup-menu(mainMenu) \n\
!Lock Ctrl <Btn1Down>: popup-menu(mainMenu) \n\
!Mod2 Ctrl <Btn1Down>: popup-menu(mainMenu) \n\
!Mod2 Lock Ctrl <Btn1Down>: popup-menu(mainMenu) \n\
~Meta <Btn1Down>: select-start() \n\
~Meta <Btn1Motion>: select-extend() \n\
!Ctrl <Btn2Down>: popup-menu(vtMenu) \n\
!Lock Ctrl <Btn2Down>: popup-m
```

The default bindings in the Tektronix window are

```
~Meta<KeyPress>: insert-seven-bit() \n\
Meta<KeyPress>: insert-eight-bit() \n\
!Ctrl <Btn1Down>: popup-menu(mainMenu) \n\
!Lock Ctrl <Btn1Down>: popup-menu(mainMenu) \n\
!Mod2 Ctrl <Btn1Down>: popup-menu(mainMenu) \n\
!Mod2 Lock Ctrl <Btn1Down>: popup-menu(mainMenu) \n\
!Ctrl <Btn2Down>: popup-menu(tekMenu) \n\
!Lock Ctrl <Btn2Down>: popup-menu(tekMenu) \n\
!Mod2 Ctrl <Btn2Down>: popup-menu(tekMenu) \n\
!Mod2 Lock Ctrl <Btn2Down>: popup-menu(tekMenu) \n\
Shift ~Meta<Btn1Down>: gin-press(L) \n\
~Meta<Btn1Down>: gin-press(l) \n\
Shift ~Meta<Btn2Down>: gin-press(M) \n\
~Meta<Btn2Down>: gin-press(m) \n\
Shift ~Meta<Btn3Down>: gin-press(R) \n\
~Meta<Btn3Down>: gin-press(r)
```

Below is a sample how of the `keymap()` action is used to add special keys for entering commonly typed works:

```
*VT100.Translations: #override <Key>F13: keymap(dbx)
VT100.dbxKeymap.translations: \
<Key>F14: keymap(None) \n\
<Key>F17: string("next") string(0x0d) \n\
<Key>F18: string("step") string(0x0d) \n\
<Key>F19: string("continue") string(0x0d) \n\
<Key>F20: string("print ") insert-selection(PRIMARY, CUT_BUFFER0)
```

ENVIRONMENT

`xterm` sets the environment variables `TERM` and `TERMCAP` properly for the size window you have created. It also uses and sets the environment variable `DISPLAY` to specify which bit map display terminal to use. The environment variable `WINDOWID` is set to the X window `id` number of the `xterm` window.

SEE ALSO

`resize(1)`, `x(1)`, `pty(4)`, `tty(4)`

Xterm Control Sequences

BUGS

Large pastes do not work on some systems. This is not a bug in `xterm`; it is a bug in the pseudo-terminal driver of those systems. `xterm` feeds large pastes to the `pty` only as fast as the `pty` will accept data, but some `pty` drivers do not return enough information to know if the write has succeeded.

Many of the options are not resettable after `xterm` starts.

Only fixed-width, character-cell fonts are supported.

This program still needs to be rewritten. It should be split into very modular sections, with the various emulators being completely separate widgets that don't know about each other. Ideally, you'd like to be able to pick and choose emulator widgets and stick them into a single control widget.

There needs to be a dialog box to allow entry of the Tek `COPY` filename.

X Version 11 Release 6

Xvfb

`xvfb`—Virtual framebuffer X server for X Version 11

SYNOPSIS

`xvfb` [option] ...

DESCRIPTION

`xvfb` is an X server that can run on machines with no display hardware and no physical input devices. It emulates a dumb framebuffer using virtual memory.

The primary use of this server is intended to be server testing. The `mfb` or `cfb` code for any depth can be exercised with this server without the need for real hardware that supports the desired depths.

A secondary use is testing clients against unusual depths and screen configurations.

OPTIONS

In addition to the normal server options described in the `Xserver(1)` manual page, `Xvfb` accepts the following command-line switches:

`-screen screennum WxHxD`

This option creates screen `screennum` and sets its width, height, and depth to `W`, `H`, and `D`, respectively. By default, only screen 0 exists and has the dimensions 1280×1024×8.

`-pixdepths list-of-depths`

This option specifies a list of pixmap depths that the server should support in addition to the depths implied by the supported screens. `list-of-depths` is a space-separated list of integers that can have values from 1 to 32.

`-fbdir framebuffer-directory`

This option specifies the directory in which the memory-mapped files containing the framebuffer memory should be created. (See “Files.”) This option only exists on machines that have the `mmap` and `msync` system calls.

`-shmем`

This option specifies that the framebuffer should be put in shared memory. The shared memory ID for each screen will be printed by the server. The shared memory is in `xwd` format. This option only exists on machines that support the System V shared memory interface.

If neither `-shmем` nor `-fbdir` is specified, the framebuffer memory will be allocated with `malloc()`.

FILES

The following file is created if the `-fbdir` option is given:

```
framebuffer-directory
/Xvfb_screen<n>
```

Memory-mapped file containing screen `n`'s framebuffer memory, one file per screen. The file is in `xwd` format.

EXAMPLES

```
Xvfb :1 -screen 0 1600x1200x32
```

The server will listen for connections as server number 1, and screen 0 will be depth 32 1600×1200.

```
Xvfb :1 -screen 1 1600x1200x16
```

The server will listen for connections as server number 1, will have the default screen configuration (one screen, 1280×1024×8), and screen 1 will be depth 16 1600×1200.

```
Xvfb -pixdepths 3 27
-fbdir /usr/tmp
```

The server will listen for connections as server number 0, will have the default screen configuration (one screen, 1280×1024×8), will also support pixmap depths of 3 and 27, and will use memory-mapped files in `/usr/tmp` for the framebuffer.

```
xwud -in /usr/tmp/Xvfb screen0
```

Displays screen 0 of the server started by the preceding example.

xvidtune

xvidtune—Video mode tuner for XFree86

SYNOPSIS

```
xvidtune [ -prev j -next j -unlock j -query j -saver suspendtime [ offtime ] ][-toolki toption ... ]
```

DESCRIPTION

xvidtune is a client interface to the XFree86 X server video mode extension (XFree86-VidModeExtension).

When given one of the nontoolkit options, xvidtune provides a command-line interface to either switch the video mode or get/set monitor powersaver time-outs.

Without any options (or with only toolkit options) it presents the user with various buttons and sliders that can be used to interactively adjust existing video modes. It will also print the settings in a format suitable for inclusion in an XF86Config file.

NOTE

The original mode settings can be restored by pressing the `r` key, and this can be used to restore a stable screen in situations where the screen becomes unreadable.

The available buttons are

Left
Right
Up
Down

Adjust the video mode so that the display will be moved in the appropriate direction:

Wider
Narrower
Shorter
Taller

Adjust the video mode so that the display size is altered appropriately:

Quit
Apply
Auto

Test
Restore
Fetch
Show

Next
Prev

Exit the program.

Adjust the current video mode to match the selected settings.

Cause the Up/Down/Right/Left, Wider/Narrower/Shorter/Taller, Restore, and the special S3 buttons to be applied immediately. This button can be toggled.

Temporarily switch to the selected settings.

Return the settings to their original values.

Query the server for its current settings.

Print the currently selected settings to stdout in XF86Config Modeline format. The primary selection is similarly set.

Switch the Xserver to the next video mode.

Switch the Xserver to the previous video mode.

For some S3-based cards (964 and 968) the following are also available:

InvertVCLK
EarlySC

Change the VCLK invert/noninvert state.

Change the Early SC state. This affects screen wrapping.

BlankDelay1, BlankDelay2

Set the blank delay values. This affects screen wrapping. Acceptable values are in the range 0–7. The values may be incremented or decremented with the + and - buttons, or by pressing the + or - keys in the text field.

For S3-864/868 based cards, InvertVCLK and BlankDelay1 may be useful. For S3 Trio32/Trio64 cards, only InvertVCLK is available. At the moment there are no default settings available for these chips in the video mode extension and thus this feature is disabled in `xvidtune`. It can be enabled by setting any of the optional S3 commands in the screen section of `XF86Config`, for example, using

```
blank delay "" 0
```

OPTIONS

`xvidtune` accepts the standard X Toolkit command-line options as well as the following:

-prev
-next
-unlock

Switch the `Xserver` to the previous video mode.

Switch the `Xserver` to the next video mode.

Normally, `xvidtune` will disable the switching of video modes via hot keys while it is running. If for some reason the program did not exit cleanly and they are still disabled, the program can be rerun with this option to reenables the mode switching key combinations.

-saver suspendtime [offtime]

Set the suspend and off screen saver inactivity time-outs. The values are in seconds.

-query

Display the monitor parameters and extended screen saver time-outs.

xwd

xwd—Dump an image of an X window

SYNOPSIS

```
xwd [-debug] [-help] [-nobdrs] [-out file] [-xy] [-frame] [-add value]
[-root j -id id j -name name ] [-icmap] [-screen] [-display display]
```

DESCRIPTION

xwd is an X Window System window dumping utility. xwd allows X users to store window images in a specially formatted dump file. This file can then be read by various other X utilities for redisplay, printing, editing, formatting, archiving, image processing, and so on. The target window is selected by clicking the pointer in the desired window. The keyboard bell is rung once at the beginning of the dump and twice when the dump is completed.

OPTIONS

-display display	This argument allows you to specify the server to connect to; see x(1).
-help	Print out the Usage: command syntax summary.
-nobdrs	This argument specifies that the window dump should not include the pixels that compose the X window border. This is useful in situations in which you may wish to include the window contents in a document as an illustration.
-out file	This argument allows the user to explicitly specify the output file on the command line. The default is to output to standard out.
-xy	This option applies to color displays only. It selects XY format dumping instead of the default Z format.
-add value	This option specifies a signed value to be added to every pixel.
-frame	This option indicates that the window manager frame should be included when manually selecting a window.
-root	This option indicates that the root window should be selected for the window dump, without requiring the user to select a window with the pointer.
-id id	This option indicates that the window with the specified resource id should be selected for the window dump, without requiring the user to select a window with the pointer.
-name name	This option indicates that the window with the specified WM_NAME property should be selected for the window dump, without requiring the user to select a window with the pointer.
-icmap	Normally, the colormap of the chosen window is used to obtain RGB values. This option forces the first installed colormap of the screen to be used instead.
-screen	This option indicates that the GetImage request used to obtain the image should be done on the root window, rather than directly on the specified window. In this way, you can obtain pieces of other windows that overlap the specified window, and more importantly, you can capture menus or other popups that are independent windows but that appear over the specified window.

X Version 11 Release 6

xwdtopnm

xwdtopnm—Convert an X11 or X10 window dump file into a portable anymap

SYNOPSIS

xwdtopnm [xwdfile]

DESCRIPTION

Reads an X11 or X10 window dump file as input. Produces a portable anymap as output. The type of the output file depends on the input file. If it's black and white, a `pbm` file is written; if it's grayscale, a `pgm` file, else a `ppm` file. The program tells you which type it is writing.

Using this program, you can convert anything on an X workstation's screen into an anymap. Just display whatever you're interested in, do an `xwd`, run it through `xwdtopnm`, and then use `pnmcut` to select the part you want.

BUGS

I haven't tested this tool with very many configurations, so there are probably bugs. Please let me know if you find any.

xwininfo

xwininfo—Window information utility for X

SYNOPSIS

```
xwininfo [-help] [-id id] [-root] [-name name] [-int] [-children] [-tree]
[-stats] [-bits] [-events] [-size] [-wm] [-shape] [-frame] [-all] [-english]
[-metric] [-display display]
```

DESCRIPTION

`xwininfo` is a utility for displaying information about windows. Various information is displayed depending on which options are selected. If no options are chosen, `-stats` is assumed.

The user has the option of selecting the target window with the mouse (by clicking any mouse button in the desired window) or by specifying its window `id` on the command line with the `-id` option. Or instead of specifying the window by its `id` number, the `-name` option may be used to specify which window is desired by name. There is also a special `-root` option to quickly obtain information on the screen's root window.

OPTIONS

<code>-help</code>	Print out the <code>Usage:</code> command syntax summary.
<code>-id id</code>	This option allows the user to specify a target window <code>id</code> on the command line rather than using the mouse to select the target window. This is very useful in debugging X applications where the target window is not mapped to the screen or where the use of the mouse might be impossible or interfere with the application.
<code>-name name</code>	This option allows the user to specify that the window <code>name</code> is the target window on the command line rather than using the mouse to select the target window.
<code>-root</code>	This option specifies that X's root window is the target window. This is useful in situations where the root window is completely obscured.
<code>-int</code>	This option specifies that all X window <code>ids</code> should be displayed as integer values. The default is to display them as hexadecimal values.
<code>-children</code>	This option causes the root, parent, and children windows' <code>ids</code> and names of the selected window to be displayed.
<code>-tree</code>	This option is like <code>-children</code> but displays all children recursively.
<code>-stats</code>	This option causes the display of various attributes pertaining to the location and appearance of the selected window. Information displayed includes the location of the window, its width and height, its depth, border width, class, colormap <code>id</code> if any, map state, backing-store hint, and location of the corners.
<code>-bits</code>	This option causes the display of various attributes pertaining to the selected window's raw bits and how the selected window is to be stored. Displayed information includes the selected window's bit gravity, window gravity, backing-store hint, backing-planes value, backing pixel, and whether or not the window has <code>save-under</code> set.
<code>-events</code>	This option causes the selected window's event masks to be displayed. Both the event mask of events wanted by some client and the event mask of events not to propagate are displayed.
<code>-size</code>	This option causes the selected window's sizing hints to be displayed. Displayed information includes the following: for both the normal size hints and the zoom size hints, the user supplied location, if any; the program supplied location, if any; the user supplied size, if any; the program supplied size, if any;

	the minimum size, if any; the maximum size, if any; the resize increments, if any; and the minimum and maximum aspect ratios, if any.
-wm	This option causes the selected window's window manager hints to be displayed. Information displayed may include whether or not the application accepts input, what the window's icon window # and name is, where the window's icon should go, and what the window's initial state should be.
-shape	This option causes the selected window's window and border shape extents to be displayed.
-frame	This option causes window manager frames to be considered when manually selecting windows.
-metric	This option causes all individual height, width, and x and y positions to be displayed in millimeters as well as number of pixels, based on what the server thinks the resolution is. Geometry specifications that are in +x+y form are not changed.
-english	This option causes all individual height, width, and x and y positions to be displayed in inches (and feet, yards, and miles if necessary) as well as number of pixels. <code>-metric</code> and <code>-english</code> may both be enabled at the same time.
-all	This option is a quick way to ask for all information possible.
-display di spl ay	This option allows you to specify the server to connect to; see <code>x(1)</code> .

EXAMPLE

The following is a sample summary taken with no options specified:

```
xwininfo: Window id: 0x60000f "xterm" Absolute upper-left X: 2
Absolute upper-left Y: 85 Relative upper-left X: 0 Relative upper-left Y: 25
Width: 579 Height: 316 Depth: 8 Visual Class: PseudoColor Border width: 0
Class: InputOutput Colormap: 0x27 (installed) Bit Gravity State:
NorthWestGravity Window Gravity State: NorthWestGravity Backing Store State:
NotUseful Save Under State: no Map State: IsViewable Override Redirect State:
no Corners: +2+85 -699+85 -699-623 +2-623 -geometry 80x24+0+58
```

ENVIRONMENT

DISPLAY

To get the default host and display number

SEE ALSO

`x(1)`, `xprop(1)`

BUGS

Using `-stats -bits` shows some redundant information.

The `-geometry` string displayed must make assumptions about the window's border width and the behavior of the application and the window manager. As a result, the location given is not always correct.

AUTHOR

Mark Lillibridge (MIT Project Athena)

xwud

xwud—Image displayer for X

SYNOPSIS

```
xwud [-in file] [-noclick] [-geometry geom] [-display di splay]
[-new] [-std <matype>] [-raw] [-vis <vis-type-or-id>] [-help] [-rv]
[-plane number] [-fg color] [-bg color]
```

DESCRIPTION

xwud is an X Window System image undumping utility. **xwud** allows X users to display in a window an image saved in a specially formatted dump file, such as produced by **xwd(1)**.

OPTIONS

<code>-bg color</code>	If a bitmap image (or a single plane of an image) is displayed, this option can be used to specify the color to display for the 0 bits in the image.
<code>-display di splay</code>	This option allows you to specify the server to connect to; see x(1) .
<code>-fg color</code>	If a bitmap image (or a single plane of an image) is displayed, this option can be used to specify the color to display for the 1 bits in the image.
<code>-geometry geom</code>	This option allows you to specify the size and position of the window. Typically, you will only want to specify the position, and let the size default to the actual size of the image.
<code>-help</code>	Print out a short description of the allowable options.
<code>-in file</code>	This option enables the user to explicitly specify the input file on the command line. If no input file is given, the standard input is assumed.
<code>-new</code>	This option forces creation of a new colormap for displaying the image. If the image characteristics happen to match those of the display, this can get the image on the screen faster, but at the cost of using a new colormap (which on most displays will cause other windows to go Technicolor).
<code>-noclick</code>	Clicking any button in the window will terminate the application, unless this option is specified. Termination can always be achieved by typing <code>q</code> , <code>Q</code> , or <code>Ctrl+C</code> .
<code>-plane number</code>	You can select a single bit plane of the image to display with this option. Planes are numbered with zero being the least significant bit. This option can be used to figure out which plane to pass to xpr(1) for printing.
<code>-raw</code>	This option forces the image to be displayed with whatever color values happen to currently exist on the screen. This option is mostly useful when undumping an image back onto the same screen that the image originally came from, while the original windows are still on the screen, and results in getting the image on the screen faster.
<code>-rv</code>	If a bitmap image (or a single plane of an image) is displayed, this option forces the foreground and background colors to be swapped. This may be needed when displaying a bitmap image that has the color sense of pixel values 0 and 1 reversed from what they are on your display.

`-std maptype`

`-vis vis-type-or-id`

This option causes the image to be displayed using the specified standard colormap. The property name is obtained by converting the type to uppercase, prepending `RGB`, and appending `MAP`. Typical types are `best`, `default`, and `gray`. See `xstd-cmap(1)` for one way of creating standard colormaps.

This option allows you to specify a particular visual or visual class. The default is to pick the “best” one. A particular class can be specified: `StaticGray`, `GrayScale`, `StaticColor`, `PseudoColor`, `DirectColor`, or `TrueColor`. Or `Match` can be specified, meaning use the same class as the source image. Alternatively, an exact visual `id` (specific to the server) can be specified, either as a hexadecimal number (prefixed with `0x`) or as a decimal number. Finally, `default` can be specified, meaning to use the same class as the colormap of the root window. Case is not significant in any of these strings.

ybmtopbm

`ybmtopbm`—Convert a Bennet Yee “face” file into a portable bitmap

SYNOPSIS

`ybmtopbm [facefile]`

DESCRIPTION

Reads a file acceptable to the `face` and `xbm` programs by Bennet Yee (`bsy+@cs.cmu.edu`). Writes a portable bitmap as output.

SEE ALSO

`pbmtoybm(1)`, `pbm(5)`, `face(1)`, `face(5)`, `xbm(1)`

ytalk

ytalk—A multiuser chat program.

SYNOPSIS

```
ytalk [-x] username...
```

DESCRIPTION

ytalk (V3.0 Patch Level 1) is in essence a multiuser chat program. It works almost exactly like the UNIX talk program and even communicates with the same talk daemon(s), but ytalk allows for multiple connections.

The `username` field may be formatted in several different ways:

name	Some user on your machine
name@host	Some user on a different machine
name#tty	Some user on a particular terminal
name#tty@host	Some user on a particular tty on a different machine
name@host#tty	Same as name#tty@host

You can specify multiple usernames on the command line, for example,

```
ytalk george fred@hissun.edu marc@grumpy.cc
```

The `-x` option disables the X11 interface (described below).

For each user on the command line, ytalk will attempt to connect to the talk daemon on the specified user's host and determine if that user has left an invitation for you to call. If not, ytalk leaves an invitation for him and tells his talk daemon to send an announcement to his screen. There is not yet a dedicated ytalk daemon, but there will be. Right now, ytalk is able to communicate with both existing versions of UNIX talk daemons. For any particular host, ytalk will attempt to communicate with a talk daemon the caller's host also supports. If the two hosts have no daemon in common, then UNIX talk will not function at all, but a connection is possible through (and only through) ytalk.

After a connection has been established between two users, they can chat back and forth to their hearts' content. The connection is terminated when one of them hits Control-C or selects Quit from the main menu.

ytalk is perfectly compatible with UNIX talk and they can even converse with each other without any problems. However, many of the features of ytalk can only operate when you are connected to a user who is also using ytalk. For the rest of this document, it will be assumed that all connected users are using ytalk unless otherwise stated.

If you specified more than one user on the ytalk command line, then ytalk will process and add each user to the conversation as they respond to your invitation. As each new user enters the conversation, the screen is further subdivided into smaller and smaller windows, one for each connected user. Right now, the number of connected users is limited by the number of lines on your terminal (or window), for each connected user needs at least three lines.

ytalk does implement primitive support of the X11 Windowing System. If the environment variable DISPLAY is set, then ytalk attempts to connect to that X server. Further details about the X11 interface (and how to turn it off) are given later in this section.

As each new user is added to the conversation, ytalk will transmit information about that user to all other connected ytalk users so that their screens will also subdivide and incorporate the new user. If the new user is using UNIX talk, then information about him will NOT be transmitted, as his screen would be unable to accept multiple connections. I have given brief thought to allowing at least the output of UNIX talk users to be transmitted to all connected ytalk users, but I have not written any code to do so. Note that even though UNIX talk cannot handle multiple connections, it is still possible for ytalk to handle multiple UNIX "talk" connections. For example, george (using ytalk) could communicate with fred and joe (both using UNIX talk), but fred and joe would be unaware of each other. The best way to understand the limitations that UNIX "talk" places on ytalk is to test various connections between the two and see how things work.

ESCAPE MENU

Whenever you are using `ytalk`, you can hit the Escape key to bring up a menu that at this moment has these options:

a	Add a user
d	Delete a user
o	Options
s	Shell
u	User list
w	Output user to file
q	Quit

By choosing option `a`, you are given the opportunity to type the name of any user you wish to include into the conversation. Again, `YTALK` will accept an invitation from that user if an invitation exists, or will leave an invitation and ring the given user.

By choosing option `d`, you can select the name of a connection to terminate.

By choosing option `o`, you can view and/or modify any of the `ytalk` options. (See the “Options” subsection for a list of `ytalk` options.)

By choosing option `s`, you can invoke a shell in your `ytalk` window. All other users will see what happens in your shell. `ytalk` will automatically resize your window down to the size of the smallest window you are connected to, in order to ensure that all users always see the same thing.

The `u` option displays a list of connected and unconnected users, as well as their window sizes and what version of talk software they are running.

By choosing option `w`, you can select any connected user and type the name of a file, and all further output from that user will be dumped to the specified file. The file, if it exists, will be overwritten. If you choose `w` and the same user again, further output to the file will be terminated.

Oh, one other thing: when user A attempts to `ytalk` to user B, but user B is already `ytalking` with user C, user A’s `ytalk` program will realize that user B is already using `ytalk`, and will communicate with user B’s `ytalk` program directly in order to initialize the conversation. User B will see a nice windowed message such as

```
Do you wish to talk with user A?
```

and he will be prompted for a yes/no answer. This, in my opinion, is much preferable to blitting the announcement message and messing up user B’s screen.

RUNTIME OPTIONS

When you select Options from the main menu, you are given the opportunity to edit the `ytalk` options. The current options are

s	Turn scrolling [off/on]
w	Turn word-wrap [off/on]
i	Turn auto-import [off/on]
v	Turn auto-invite [off/on]
r	Turn auto-rering [off/on]
a	Turn asides [off/on]

If `scrolling` is turned on, then a user’s window will scroll when he reaches the bottom, instead of wrapping back around to the top.

If `word-wrap` is turned on, then any word that would overextend the right margin will be automatically moved to the next line on your screen.

If `auto-import` is turned on, then `ytalk` will assume that you wish to talk to any users that connect to other `ytalk` users that are connected to you. That last sentence does make sense; try again. `ytalk` will add these users to your session automatically, without asking you for verification.

If `auto-invite` is turned on, then `ytalk` will automatically accept any connection requested by another user and add the user to your session. You will not be asked for verification.

If `auto-rering` is turned on, then `ytalk` will automatically re-ring any user who does not respond to your invitation within 30 seconds. You will not be asked for verification.

If `asides` is turned on (it may not be available), then keyboard input received while the input focus is in a specific user's window will only be sent to that user. (See the "X11 Interface" subsection.)

Any of these options can be set to your preference in your `.ytalkrc` file, as described in the next subsection.

YTALK STARTUP FILE

If your home directory contains a file named `.ytalkrc`, then `ytalk` will read this file while starting up. All `ytalk` runtime options, as well as some startup options, can be set in this file.

SETTING BOOLEAN OPTIONS

Boolean options can be preset with the following syntax:

```
turn option [off | on]
```

where `option` is one of `scrolling`, `word-wrap`, `auto-import`, `auto-invite`, `auto-rering`, `asides`, or `X`. Setting these options works just like described earlier in this section. Turning `x` on or off will enable or disable the X11 Interface. For example, one could enable `word-wrap` with the line:

```
turn word-wrap on
```

SETTING READDRESS MODES

The purpose of readdressing is to allow `ytalk` connections across point-to-point network gateways where the local machines know themselves by a different address (and typically hostname) than the remote machines. The basic syntax of a `readdress` command is this:

```
readdress from-address to-address domain
```

The `readdress` statement simply makes a claim that the machine(s) in `domain` communicate with the machine(s) at `from-address` by sending a packet to `to-address`. Because most users have no use for this whatsoever, I'll describe it only briefly.

THIS IS NOT ROUTING. For example, my machine at home is connected via PPP to the network at my office. My machine at home thinks its Ethernet address is `192.188.253.1` and its hostname is `"talisman.com"`. The network at my office has the address `192.67.141.0`. When I'm connected via PPP, my home machine is placed into the office network as address `192.67.141.9` with hostname `"talisman.austin.eds.com"`.

`ytalk` needs to know that if it is running on domain `192.67.141.0` and receives packets from `192.188.253.1` that it should respond to `192.67.141.9`, not `192.188.253.1`. Right? Right. Okay, okay, okay. I put this line into my `.ytalkrc` on both ends:

```
readdress talisman talisman.austin.eds.com 192.67.141.0
```

On my home end, this translates to

```
readdress 192.188.253.1 192.67.141.9 192.67.141.0
```

which tells my home machine to advertise itself as `192.67.141.9` instead of `192.188.253.1` when `y` talking to machines on the network `192.67.141.0`. On the office end, the `readdress` command translates to

```
readdress 192.67.141.9 192.67.141.9 192.67.141.0
```

which the office machines basically ignore.

Enough. For more information on how to use this, consult the source code or send me a letter. :-)

X11 INTERFACE

If the `DISPLAY` environment variable is defined when `ytalk` starts up, then `ytalk` will attempt to communicate with that X server. A window will be created for you and each user you are connected to. The X11 Interface can be disabled either by specifying `-x` on the command line or by putting this line into your `.ytalkrc` file:

```
turn X off
```

A window is created for each individual user in the conversation. If the input focus is in the main window (the one with `ytalk` in the title bar) then anything typed will be sent to all connected users. If the input focus is in one of the user's windows, then anything typed will be sent as an aside to only that user. If the `aside` option is turned off, then `ytalk` will beep and not accept anything typed when the input focus is not in the main window.

`ytalk` consults the X11 Resource Database for these user-definable configuration options:

`ytalk.display`: X server to connect to, defaulting to the `DISPLAY` environment variable.

`ytalk.reverse`: Reverse black/white pixels.

`ytalk.font`: Font to use, defaulting to `9x15`.

`ytalk.geometry`: Window size, defaulting to `80x24`.

FUTURE WORK

Work is being done on the following ideas:

- Private conversations that do not get interrupted or transmitted to all `ytalk` connections
- A dedicated `ytalk` daemon

FILES

`/usr/local/etc/ytalkrc`

`$HOME/.ytalkrc`

Systemwide defaults file.

User's local configuration file. This file overrides options set in the system `ytalkrc` file.

CONTRIBUTORS

Special thanks to Carl Edman for numerous code patches, beta testing, and comments. I think this guy spends as much time on `ytalk` as I do. Special thanks to Tobias Hahn and Geoff W. for beta testing and suggestions. Thanks to Sitaram Ramaswamy for the original `ytalk` man page. Thanks to Magnus Hammerin for Solaris 2.* support. Thanks to Jonas Yngvesson for `aside` messages in X. Thanks to Andreas Stolcke for fixing the X resource database calls. Thanks to John Vanderpool, Shih-Chen Huang, Andrew Myers, Duncan Sinclair, Evan McLean, and Larry Schwimmer for comments and ideas. The `README` file shipped with `ytalk` gives detailed attributions.

BUGS

If you have any ideas, comments, or questions, I'd be happy to hear from you at ytalk@austin.eds.com.

24 June 1993

yuvplittoppm

`yuvplittoppm`—Convert a `Y-`, a `U-`, and a `V-` file into a portable pixmap.

SYNOPSIS

```
yuvplittoppm basename width height [-ccir601]
```

DESCRIPTION

Reads three files, containing the YUV components, as input. These files are `basename.Y`, `basename.U` and `basename.V`. Produces a portable pixmap on `stdout`.

Since the YUV files are raw files, the dimensions width and height must be specified on the command line.

OPTIONS

`-ccir601`

Assumes that the YUV triplets are scaled into the smaller range of the CCIR 601 (MPEG) standard. Otherwise, the JFIF (JPEG) standard is assumed.

yuvtoppm

`yuvtoppm`—Convert Abekas YUV bytes into a portable pixmap

SYNOPSIS

```
yuvtoppm width height [imagedata]
```

DESCRIPTION

Reads raw Abekas YUV bytes as input. Produces a portable pixmap as output. The input file is just YUV bytes. You have to specify the width and height on the command line, since the program obviously can't get them from the file. The `maxval` is assumed to be 255.

zcmp, zdiff

`zcmp`, `zdiff`—Compare compressed files

SYNOPSIS

```
zcmp [ cmp_options ] file1 [ file2 ]
zdiff [diff_options ] file1 [ file2 ]
```

DESCRIPTION

`zcmp` and `zdiff` are used to invoke the `cmp` or the `diff` program on compressed files. All options specified are passed directly to `cmp` or `diff`. If only one file is specified, then the files compared are `file1` and an uncompressed `file1.gz`. If two files are specified, then they are uncompressed if necessary and fed to `cmp` or `diff`. The exit status from `cmp` or `diff` is preserved.

SEE ALSO

`cmp(1)`, `diff(1)`, `zmore(1)`, `zgrep(1)`, `znew(1)`, `zforce(1)`, `gzip(1)`, `gzexe(1)`

BUGS

Messages from the `cmp` or `diff` programs refer to temporary filenames instead of those specified.

zeisstopnm

`zeisstopnm`—Convert a Zeiss confocal file into a portable anymap

SYNOPSIS

```
zeisstopnm [-pgm j -ppm][zeissfile]
```

DESCRIPTION

Reads a Zeiss confocal file as input. Produces a portable anymap as output. The type of the output file depends on the input file—if it's grayscale, a `pgm` file will be produced; otherwise, it will be a `ppm` file. The program tells you which type it is writing.

OPTIONS

<code>-pgm</code>	Force the output to be a <code>pgm</code> file
<code>-ppm</code>	Force the output to be a <code>ppm</code> file

SEE ALSO

`pnm(5)`

zforce

`zforce`—Force a `.gz` extension on all `gzip` files

SYNOPSIS

```
zforce [ name ... ]
```

DESCRIPTION

`zforce` forces a `.gz` extension on all `gzip` files so that `gzip` will not compress them twice. This can be useful for files with names truncated after a file transfer. On systems with a 14-character limitation on filenames, the original name is truncated to make room for the `.gz` suffix. For example, `12345678901234` is renamed to `12345678901.gz`. A filename such as `foo.tgz` is left intact.

SEE ALSO

gzip(1), znew(1), zmore(1), zgrep(1), zdiff(1), gzexe(1)

zgrep

zgrep—Search possibly compressed files for a regular expression

SYNOPSIS

```
zgrep [ grep_options ] [-e] pattern filename...
```

DESCRIPTION

zgrep is used to invoke the grep on compressed or gzipped files. All options specified are passed directly to grep. If no file is specified, then the standard input is decompressed if necessary and fed to grep. Otherwise, the given files are uncompressed if necessary and fed to grep.

If zgrep is invoked as zegrep or zfgrep, then egrep or fgrep is used instead of grep. If the GREP environment variable is set, zgrep uses it as the grep program to be invoked. For example,

```
for sh: GREP=fgrep zgrep string files for csh: (setenv GREP fgrep; zgrep string files)
```

AUTHOR

zmore

zmore—File perusal filter for crt viewing of compressed text

SYNOPSIS

```
zmore [ name ... ]
```

DESCRIPTION

zmore is a filter that allows examination of compressed or plain text files one screenful at a time on a soft-copy terminal. zmore works on files compressed with compress, pack, or gzip, and also on uncompressed files. If a file does not exist, zmore looks for a file of the same name with the addition of a .gz, .z, or .Z suffix.

zmore normally pauses after each screenful, printing -More- at the bottom of the screen. If the user then types a carriage return, one more line is displayed. If the user hits a space, another screenful is displayed. Other possibilities are enumerated later.

zmore looks in the file /etc/termcap to determine terminal characteristics, and to determine the default window size. On a terminal capable of displaying 24 lines, the default window size is 22 lines. To use a pager other than the default more, set environment variable PAGER to the name of the desired program, such as less.

Other sequences that may be typed when zmore pauses, and their effects, are as follows (i is an optional integer argument, defaulting to 1) :

i <space>	Display i more lines, (or another screenful if no argument is given).
^D	Display 11 more lines (a "scroll"). If i is given, then the scroll size is set to i.
d	Same as ^D (control-D)

<code>i z</code>	Same as typing a space except that <code>i</code> , if present, becomes the new window size. Note that the window size reverts back to the default at the end of the current file.
<code>i s</code>	Skip <code>i</code> lines and print a screenful of lines.
<code>i f</code>	Skip <code>i</code> screenfuls and print a screenful of lines.
<code>q or Q</code>	Quit reading the current file; go on to the next (if any).
<code>e or q</code>	When the prompt <code>-More-(Next file: file)</code> is printed, this command causes <code>zmore</code> to exit.
<code>s</code>	When the prompt <code>-More-(Next file: file)</code> is printed, this command causes <code>zmore</code> to skip the next file and continue.
<code>=</code>	Display the current line number.
<code>i /expr</code>	Search for the <code>i</code> th occurrence of the regular expression <code>expr</code> . If the pattern is not found, <code>zmore</code> goes on to the next file (if any). Otherwise, a screenful is displayed, starting two lines before the place where the expression was found. The user's erase and kill characters may be used to edit the regular expression. Erasing back past the first column cancels the <code>search</code> command.
<code>i n</code>	Search for the <code>i</code> th occurrence of the last regular expression entered.
<code>!command</code>	Invoke a shell with <code>command</code> . The character <code>!</code> in <code>command</code> is replaced with the previous shell command. The sequence <code>\!</code> is replaced by <code>!</code> .
<code>:q or :Q</code>	Quit reading the current file; go on to the next (if any) (same as <code>q</code> or <code>Q</code>).
<code>.</code>	(dot) Repeat the previous command.

The commands take effect immediately; that is, it is not necessary to type a carriage return. Up to the time when the command character itself is given, the user may hit the line kill character to cancel the numerical argument being formed. In addition, the user may hit the erase character to redisplay the `-More-` message.

At any time when output is being sent to the terminal, the user can hit the quit key (normally `Control-n`). `zmore` will stop sending output, and will display the usual `-More-` prompt. The user may then enter one of the preceding commands in the normal manner. Unfortunately, some output is lost when this is done because any characters waiting in the terminal's output queue are flushed when the quit signal occurs.

The terminal is set to `noecho` mode by this program so that the output can be continuous. What you type will thus not show on your terminal, except for the `/` and `!` commands.

If the standard output is not a teletype, then `zmore` acts just like `zcat`, except that a header is printed before each file.

FILES

`/etc/termcap` Terminal database

znew

`znew`—Recompress Z files to GZ files

SYNOPSIS

`znew [-ftv9PK] [name.Z ...]`

DESCRIPTION

`znew` recompresses files from Z (`compress`) format to GZ (`gzip`) format. If you want to recompress a file already in `gzip` format, rename the file to force a `.z` extension, then apply `znew`.

OPTIONS

<code>-f</code>	Force recompression from Z to GZ format even if a GZ file already exists.
<code>-t</code>	Test the new files before deleting originals.
<code>-v</code>	Verbose. Display the name and percentage reduction for each file compressed.
<code>-9</code>	Use the slowest compression method (optimal compression).
<code>-P</code>	Use pipes for the conversion to reduce disk space usage.
<code>-K</code>	Keep a Z file when it is smaller than the GZ file.

SEE ALSO

`gzip(1)`, `zmore(1)`, `zdiff(1)`, `zgrep(1)`, `zforce(1)`, `gzexe(1)`, `compress(1)`

BUGS

`znew` does not maintain the timestamp with the `-P` option if `cpmod(1)` is not available and `touch(1)` does not support the `-r` option.

Part II:

System Calls

intro

intro—Introduction to system calls

DESCRIPTION

This chapter describes the Linux system calls.

CALLING DIRECTLY

In most cases, it is unnecessary to invoke a system call directly, but there are times when the standard C library does not implement a nice function call for you.

SYNOPSIS

```
#include <linux/unistd.h>
```

A `_syscall` macro

Desired system call

SETUP

The important thing to know about a system call is its prototype. You need to know how many arguments, their types, and the function return type. Six macros make the actual call into the system easier. They have the form

```
syscallX(type,name,type1,arg1,type2,arg2,...)
```

where

X	0–5, which are the number of arguments taken by the system call
type	The return type of the system call
name	The name of the system call
typeN	The Nth argument's type
argN	The name of the Nth argument

These macros create a function called `name` with the arguments you specify. Once you include `_syscall()` in your source file, you call the system call by `name`.

EXAMPLE

```
{
    struct sysinfo s_info;
    int error;

    error = sysinfo(&s_info);
    printf("code error = %d\n", error);
    printf("Uptime = %ds\nLoad: 1 min %d / 5 min %d / 15 min %d\n"
          "RAM: total %d / free %d / shared %d\n"
          "Memory in buffers = %d\nSwap: total %d / free %d\n"
          "Number of processes = %d\n",
          s_info.uptime, s_info.loads[0],
          s_info.loads[1], s_info.loads[2],
          s_info.totalram, s_info.freeram,
          s_info.sharedram, s_info.bufferram,
          s_info.totalswap, s_info.freeswap,
          s_info.procs);
    return(0);
}
```

SAMPLE OUTPUT

```
code error = 0
uptime = 502034s
Load: 1 min 13376 / 5 min 5504 / 15 min 1152
RAM: total 15343616 / free 827392 / shared 8237056
Memory in buffers = 5066752
Swap: total 27881472 / free 24698880
Number of processes = 40
```

NOTES

The `_syscall()` macros *do not* produce a prototype. You might have to create one, especially for C++ users.

System calls are not required to return only positive or negative error codes. You need to read the source to be sure how it will return errors. Usually, it is the negative of a standard error code, for example, `-EPERM`. The `_syscall()` macros will return the result `r` of the system call when `r` is nonnegative, but will return `-1` and set the variable `errno` to `-r` when `r` is negative.

Some system calls, such as `mmap`, require more than five arguments. These are handled by pushing the arguments on the stack and passing a pointer to the block of arguments.

When defining a system call, the argument types *must* be passed by value or by pointer (for aggregates such as structs).

FILES

```
/usr/include/linux/unistd.h
```

Linux 1.2.13, 22 May 1996

exit

`exit`—Terminate the current process

SYNOPSIS

```
#include <unistd.h>
void exit(int status);
```

DESCRIPTION

`exit` terminates the calling process immediately. Any open file descriptors belonging to the process are closed; any children of the process are inherited by process 1, `init`, and the process's parent is sent a `SIGCHLD` signal.

`status` is returned to the parent process as the process's exit status and can be collected using one of the `wait` family of calls.

RETURN VALUE

`exit` never returns.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

NOTES

`exit` does not call any functions registered with the ANSI C `atexit` function and does not flush standard I/O buffers. To do these things, use `exit(3)`.

fork(2), execve(2), waitpid(2), wait4(2), kill(2), wait(3), exit(3)

Linux, 21 July 1993

accept

accept—Accept a connection on a socket

SYNOPSIS

```
#include <sys/types.h>
#include <sys/socket.h>
int accept(int s, struct sockaddr *addr, int*addrlen);
```

DESCRIPTION

The argument `s` is a socket that has been created with `socket(2)`, bound to an address with `bind(2)`, and is listening for connections after a `listen(2)`. The `accept` function extracts the first connection request on the queue of pending connections, creates a new socket with the same properties of `s`, and allocates a new file descriptor for the socket. If no pending connections are present on the queue and the socket is not marked as nonblocking, `accept` blocks the caller until a connection is present. If the socket is marked nonblocking and no pending connections are present on the queue, `accept` returns an error as described below. The accepted socket may not be used to accept more connections. The original socket `s` remains open.

The argument `addr` is a result parameter that is filled in with the address of the connecting entity, as known to the communications layer. The exact format of the `addr` parameter is determined by the domain in which the communication is occurring. The `addrlen` is a value-result parameter; it should initially contain the amount of space pointed to by `addr`; on return it will contain the actual length (in bytes) of the address returned. This call is used with connection-based socket types, currently with `SOCK_STREAM`.

It is possible to `select(2)` a socket for the purposes of doing an `accept` by selecting it for read.

For certain protocols that require an explicit confirmation, such as ISO and `DATAKIT`, `accept` can be thought of as merely dequeuing the next connection request and not implying confirmation. Confirmation can be implied by a normal read or write on the new file descriptor, and rejection can be implied by closing the new socket.

One can obtain user connection request data without confirming the connection by issuing a `recvmsg(2)` call with a `msg_iovlen` of 0 and a nonzero `msg_controllen`, or by issuing a `getsockopt(2)` request. Similarly, one can provide user connection rejection information by issuing a `sendmsg(2)` call providing only the control information, or by calling `setsockopt(2)`.

RETURN VALUES

The call returns `-1` on error. If it succeeds, it returns a nonnegative integer that is a descriptor for the accepted socket.

ERRORS

<code>EBADF</code>	The descriptor is invalid.
<code>ENOTSOCK</code>	The descriptor references a file, not a socket.
<code>EOPNOTSUPP</code>	The referenced socket is not of type <code>SOCK_STREAM</code> .
<code>EFAULT</code>	The <code>addr</code> parameter is not in a writable part of the user address space.
<code>EWOULDBLOCK</code>	The socket is marked nonblocking and no connections are present to be accepted.

HISTORY

The `accept` function appeared in BSD 4.2.

access

access—Checks user's permissions for a file

SYNOPSIS

```
#include <unistd.h>
int access(const char *pathname, int mode);
```

DESCRIPTION

access checks whether the process would be allowed to read, write, or test for existence of the file (or other file system object) whose name is *pathname*. If *pathname* is a symbolic link, permissions of the file referred by this symbolic link are tested.

mode is a mask consisting of one or more of R_OK, W_OK, X_OK, and F_OK.

R_OK, W_OK, and X_OK request checking whether the file exists and has read, write, and execute permissions, respectively. F_OK just requests checking for the existence of the file.

The tests depend on the permissions of the directories occurring in the path to the file, as given in *pathname*, and on the permissions of directories and files referred by symbolic links encountered on the way.

The check is done with the process's real UID and GID, rather than with the effective IDs as is done when actually attempting an operation. This is to allow set-UID programs to easily determine the invoking user's authority.

Only access bits are checked, not the file type or contents. Therefore, if a directory is found to be "writable," it probably means that files can be created in the directory, and not that the directory can be written as a file. Similarly, a DOS file may be found to be "executable," but the `execve(2)` call will still fail.

RETURN VALUE

On success (all requested permissions granted), 0 is returned. On error (at least 1 bit in *mode* asked for a permission that is denied, or some other error occurred), -1 is returned and `errno` is set appropriately.

ERRORS

EACCES	The requested access would be denied, either to the file itself or one of the directories in <i>pathname</i> .
EFAULT	<i>pathname</i> points outside your accessible address space.
EINVAL	mode was incorrectly specified.
ENAMETOOLONG	<i>pathname</i> is too long.
ENOENT	A directory component in <i>pathname</i> would have been accessible but does not exist or was a dangling symbolic link.
ENOTDIR	A component used as a directory in <i>pathname</i> is not, in fact, a directory.
ENOMEM	Insufficient kernel memory was available.
ELOOP	<i>pathname</i> contains a reference to a circular symbolic link, that is, a symbolic link containing a reference to itself.

RESTRICTIONS

access returns an error if any of the access types in the requested call fails, even if other types might be successful. access may not work correctly on NFS file systems with UID mapping enabled because UID mapping is done on the server and hidden from the client, which checks permissions.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

Linux 1.2.13, 17 March 1996

acct

acct—Switches process accounting on or off

SYNOPSIS

```
#include <unistd.h>
int acct(const char *filename);
```

DESCRIPTION

Warning: Since this function is not implemented as of Linux 0.99.11, it will always return `-1` and set `errno` to `ENOSYS`. If `acctkit` is installed, the function performs as advertised.

When called with the name of an existing file as argument, accounting is turned on and records for each terminating process are appended to `filename` as it terminates. An argument of `NULL` causes accounting to be turned off.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

NOTES

No accounting is produced for programs running when a crash occurs. In particular, nonterminating processes are never accounted for.

SEE ALSO

acct(5)

Linux 0.99.11, 10 August 1993

adjtimex

adjtimex—Tunes kernel clock

SYNOPSIS

```
#include <sys/timex.h>
int adjtimex(struct timex *buf);
```

DESCRIPTION

Linux uses David Mill's clock adjustment algorithm. `adjtimex` reads and optionally sets adjustment parameters for this algorithm.

`adjtimex` takes a pointer to a `timex` structure, updates kernel parameters from field values, and returns the same structure with current kernel values. This structure is declared as follows:

```

struct timex
{
    int mode;           /* mode selector */
    long offset;       /* time offset (usec) */
    long frequency;    /* frequency offset (scaled ppm) */
    long maxerror;     /* maximum error (usec) */
    long esterror;     /* estimated error (usec) */
    int status;        /* clock command/status */
    long time_constant; /* pll time constant */
    long precision;    /* clock precision (usec) (read only) */
    long tolerance;    /* clock frequency tolerance (ppm)
                       (read only) */
    struct timeval time; /* (read only) */
    long tick;         /* usecs between clock ticks */
};

```

The `mode` field determines which parameters, if any, to set. It may contain a bitwise-or combination of zero or more of the following bits:

```

#define ADJ_OFFSET      0x0001 /* time offset */
#define ADJ_FREQUENCY  0x0002 /* frequency offset */
#define ADJ_MAXERROR   0x0004 /* maximum time error */
#define ADJ_ESTERROR   0x0008 /* estimated time error */
#define ADJ_STATUS     0x0010 /* clock status */
#define ADJ_TIMECONST  0x0020 /* pll time constant */
#define ADJ_TICK       0x4000 /* tick value */
#define ADJ_OFFSET_SINGLESHOT 0x8001 /* old-fashioned adjtime */

```

Ordinary users are restricted to a 0 value for `mode`. Only the superuser may set any parameters.

RETURN VALUE

On success, `adjtimex` returns the value of `buf.status`:

```

#define TIME_OK 0 /* clock synchronized */
#define TIME_INS 1 /* insert leap second */
#define TIME_DEL 2 /* delete leap second */
#define TIME_OOP 3 /* leap second in progress */
#define TIME_BAD 4 /* clock not synchronized */

```

On failure, `adjtimex` returns `-1` and sets `errno`.

ERRORS

EFAULT	<code>buf</code> does not point to writable memory.
EPERM	<code>buf.mode</code> is nonzero and the user is not superuser.
EINVAL	An attempt is made to set <code>buf.offset</code> to a value outside the range <code>-131071</code> to <code>+131071</code> , or to set <code>buf.status</code> to a value other than those listed above, or to set <code>buf.tick</code> to a value outside the range <code>900000/HZ</code> to <code>1100000/HZ</code> , where <code>HZ</code> is the system timer interrupt frequency.

SEE ALSO

`settimeofday(2)`

alarm

`alarm`—Sets an alarm clock for delivery of a signal

SYNOPSIS

```
#include <unistd.h>
unsigned int alarm(unsigned int seconds);
```

DESCRIPTION

`alarm` arranges for a `SIGALRM` signal to be delivered to the process in `seconds` seconds.

If `seconds` is 0, no new `alarm` is scheduled.

In any event, any previously set `alarm` is canceled.

RETURN VALUE

`alarm` returns the number of seconds remaining until any previously scheduled alarm was due to be delivered, or 0 if there was no previously scheduled alarm.

NOTES

`alarm` and `setitimer` share the same timer; calls to one will interfere with use of the other.

Scheduling delays can, as ever, cause the execution of the process to be delayed by an arbitrary amount of time.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

SEE ALSO

Linux, 21 July 1993

bdflush

`bdflush`—Starts, flushes, or tunes the buffer-dirty-flush daemon

SYNOPSIS

```
int bdflush(int func, long *address);
int bdflush(int func, long data);
```

DESCRIPTION

`bdflush` starts, flushes, or tunes the buffer-dirty-flush daemon. Only the superuser may call `bdflush`.

If `func` is negative or 0 and no daemon has been started, `bdflush` enters the daemon code and never returns.

If `func` is 1, some dirty buffers are written to disk.

If `func` is 2 or more and is even (low bit is 0), `address` is the address of a long word, and the tuning parameter numbered $(\text{func}-2)/2$ is returned to the caller in that address.

If `func` is 3 or more and is odd (low bit is 1), `data` is a long word and the kernel sets tuning parameter numbered $(\text{func}-3)/2$ to that value.

The set of parameters, their values, and their legal ranges are defined in the kernel source file `fs/buffer.c`.

RETURN VALUE

If `func` is negative or 0 and the daemon successfully starts, `bindflush` never returns. Otherwise, the return value is 0 on success and -1 on failure, with `errno` set to indicate the error.

ERRORS

EPERM	Caller is not superuser.
EFAULT	<code>address</code> points outside your accessible address space.
EBUSY	An attempt was made to enter the daemon code after another process has already been entered.
EINVAL	An attempt was made to read or write an invalid parameter number, or to write an invalid value to a parameter.

Linux 1.2.4, 15 April 1995

bind

`bind`—Binds a name to a socket

SYNOPSIS

```
#include <sys/types.h>
#include <sys/socket.h>
int bind(int sockfd, struct sockaddr *my_addr, int addrlen);
```

DESCRIPTION

`bind` gives the socket, `sockfd`, the local address `my_addr`. `my_addr` is `addrlen` bytes long. Traditionally, this is called assigning a name to a socket. (When a socket is created with `socket(2)`, it exists in a name space—an address family—but has no name assigned.)

NOTES

Binding a name in the UNIX domain creates a socket in the file system that must be deleted by the caller—using `unlink(2)`—when it is no longer needed.

The rules used in name binding vary between communication domains. Consult the manual entries in section 4 for detailed information.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

EBADF	<code>sockfd</code> is not a valid descriptor.
EINVAL	The socket is already bound to an address. This may change in the future. See <code>linux/unix/socket.c</code> for details.
EACCES	The address is protected and the user is not the superuser.

The following errors are specific to UNIX domain (AF_UNIX) sockets:

EINVAL	<code>addrlen</code> was wrong, or the socket was not in the AF_UNIX family.
EROFS	The socket inode would reside on a read-only file system.
EFAULT	<code>my_addr</code> points outside your accessible address space.

ENAMETOOLONG	<code>my_addr</code> is too long.
ENOENT	The file does not exist.
ENOMEM	Insufficient kernel memory was available.
ENOTDIR	A component of the path prefix is not a directory.
EACCES	Search permission is denied on a component of the path prefix.
ELOOP	<code>my_addr</code> contains a circular reference (that is, via a symbolic link).

HISTORY

The `bind` function call appeared in BSD 4.2.

SEE ALSO

brk, sbrk

`brk`, `sbrk`—Change data segment size

SYNOPSIS

```
#include <unistd.h>
int brk(void *end_data_segment);
void *sbrk(ptrdiff_t increment);
```

DESCRIPTION

`brk` sets the end of the data segment to the value specified by `end_data_segment`.

`end_data_segment` must be greater than the end of the text segment and it must be 16KB before the end of the stack.

`sbrk` increments the program's data space by `increment` bytes. `sbrk` isn't a system call; it is just a C library wrapper.

RETURN VALUE

On success, `brk` returns 0, and `sbrk` returns a pointer to the start of the new area. On error, -1 is returned and `errno` is set to `ENOMEM`.

CONFORMS TO

BSD 4.3

`brk` and `sbrk` are not defined in the C standard and are deliberately excluded from the POSIX.1 standard (see paragraphs B.1.1.1.3 and B.8.3.3).

cacheflush

`cacheflush`—Flushes contents of the instruction and/or data cache

SYNOPSIS

```
#include <asm/cachectl.h>
int cacheflush(char *addr,intnbytes,intcache);
```

DESCRIPTION

`cacheflush` flushes contents of indicated cache(s) for user addresses in the range `addr` to `(addr+nbytes-1)`. The cache may be one of the following:

ICACHE	Flush the instruction cache.
DCACHE	Write back to memory and invalidate the affected valid cache lines.
BCACHE	Same as (ICACHE DCACHE).

RETURN VALUE

`cacheflush` returns 0 on success or -1 on error. If errors are detected, `errno` will indicate the error.

ERRORS

EINVAL	The cache parameter is not one of ICACHE, DCACHE, or BCACHE.
EFAULT	Some or all of the address range <code>addr</code> to <code>(addr+nbytes-1)</code> is not accessible.

BUGS

The current implementation ignores the `addr` and `nbytes` parameters. Therefore, the whole cache is always flushed.

NOTE

This system call is only available on MIPS-based systems.

SEE ALSO

`cachectl(2)`

Linux, 27 June 95

chdir, fchdir

`chdir, fchdir`—Changes the working directory

SYNOPSIS

```
#include <unistd.h>
int chdir(const char *path);
int fchdir(int fd);
```

DESCRIPTION

`chdir` changes the current directory to that specified in `path`.

`fchdir` is identical to `chdir`, only the directory is given as an open file descriptor.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

Depending on the file system, other errors can be returned. The more general errors are listed here:

EPERM	The process does not have execute permission on the directory.
EFAULT	<code>path</code> points outside your accessible address space.
ENAMETOOLONG	<code>path</code> is too long.

EBADF	<code>fd</code> is not a valid file descriptor.
ENOENT	The file does not exist.
ENOMEM	Insufficient kernel memory was available.
ENOTDIR	A component of the path prefix is not a directory.
EACCES	Search permission is denied on a component of the path prefix.
ELOOP	<code>path</code> contains a circular reference (that is, via a symbolic link)

SEE ALSO

`getcwd(3)`, `chroot(2)`

Linux 1.2.4, 15 April 1995

chmod, fchmod

`chmod`, `fchmod`—Changes permissions of a file

SYNOPSIS

```
#include <sys/types.h>
#include <sys/stat.h>
int chmod(const char *path, mode_t mode);
int fchmod(int fd, mode_t mode);
```

DESCRIPTION

The mode of the file given by `path` or referenced by `fd` is changed.

Modes are specified by oring the following:

<code>S_ISUID</code>	04000	Set user ID on execution
<code>S_ISGID</code>	02000	Set group ID on execution
<code>S_ISVTX</code>	01000	Sticky bit
<code>S_IRUSR</code> (<code>S_IREAD</code>)	00400	Read by owner
<code>S_IWUSR</code> (<code>S_IWRITE</code>)	00200	Write by owner
<code>S_IXUSR</code> (<code>S_IEXEC</code>)	00100	Execute/search by owner
<code>S_IRGRP</code>	00040	Read by group
<code>S_IWGRP</code>	00020	Write by group
<code>S_IXGRP</code>	00010	Execute/search by group
<code>S_IROTH</code>	00004	Read by others
<code>S_IWOTH</code>	00002	Write by others
<code>S_IXOTH</code>	00001	Execute/search by others

The effective UID of the process must be 0 or must match the owner of the file.

The effective UID or GID must be appropriate for setting execution bits.

Depending on the file system, set user ID and set group ID execution bits may be turned off if a file is written. On some file systems, only the superuser can set the sticky bit, which may have a special meaning (that is, for directories, a file can only be deleted by the owner or the superuser).

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

Depending on the file system, other errors can be returned. The more general errors for `chmod` are listed here:

EPERM	The effective UID does not match the owner of the file and is not 0.
EROFS	The named file resides on a read-only file system.
EFAULT	<code>path</code> points outside your accessible address space.
ENAMETOOLONG	<code>path</code> is too long.
ENOENT	The file does not exist.
ENOMEM	Insufficient kernel memory was available.
ENOTDIR	A component of the path prefix is not a directory.
EACCES	Search permission is denied on a component of the path prefix.
ELOOP	<code>path</code> contains a circular reference (that is, via a symbolic link)

The general errors for `fchmod` are listed here:

EBAADF	The descriptor is not value.
ENOENT	See above.
EPERM	See above.
EROFS	See above.

SEE ALSO

`open(2)`, `chown(2)`, `stat(2)`

Linux 0.99.11, 21 July 1993

chown, fchown

`chown, fchown`—Changes ownership of a file

SYNOPSIS

```
#include <sys/types.h>
#include <unistd.h>
int chown(const char *path, uid_t owner, gid_t group);
int fchown(int fd, uid_t owner, gid_t group);
```

DESCRIPTION

The owner of the file specified by `path` or by `fd` is changed. Only the superuser may change the owner of a file. The owner of a file may change the group of the file to any group of which that owner is a member. The superuser may change the group arbitrarily.

If the `owner` or `group` is specified as `-1`, that ID is not changed.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

Depending on the file system, other errors can be returned. The more general errors for `chown` are listed here:

EPERM	The effective UID does not match the owner of the file, and is not 0; or the <code>owner</code> or <code>group</code> were specified incorrectly.
EROFS	The named file resides on a read-only file system.
EFAULT	<code>path</code> points outside your accessible address space.

ENAMETOOLONG	path is too long.
ENOENT	The file does not exist.
ENOMEM	Insufficient kernel memory was available.
ENOTDIR	A component of the path prefix is not a directory.
EACCES	Search permission is denied on a component of the path prefix.
ELOOP	path contains a circular reference (that is, via a symbolic link).

The general errors for `fchown` are listed here:

EBADF	The descriptor is not value.
ENOENT	See above.
EPERM	See above.
EROFS	See above.

NOTES

`chown` does not follow symbolic links. The prototype for `fchown` is only available if `USE BSD` is defined.

SEE ALSO

`chmod(2)`, `flock(2)`

Linux 0.99.11, 21 July 1993

chroot

`chroot`—Changes root directory

SYNOPSIS

```
#include <unistd.h>
int chroot(const char *path);
```

DESCRIPTION

`chroot` changes the root directory to that specified in `path`. This directory will be used for pathnames beginning with `/`. The root directory is inherited by all children of the current process.

Only the superuser may change the root directory.

Note that this call does not change the current working directory, so that `.` can be outside the tree rooted at `/`.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

Depending on the file system, other errors can be returned. The more general errors are listed here:

EPERM	The effective UID does not match the owner of the file, and is not 0; or the owner or group were specified incorrectly.
EROFS	The named file resides on a read-only file system.
EFAULT	path points outside your accessible address space.
ENAMETOOLONG	path is too long.
ENOENT	The file does not exist.
ENOMEM	Insufficient kernel memory was available.

ENOTDIR	A component of the path prefix is not a directory.
EACCES	Search permission is denied on a component of the path prefix.
ELOOP	path contains a circular reference (that is, via a symbolic link)

chdir(2)

Linux 1.1.46, 21 August 1994

clone

clone—Creates a child process

SYNOPSIS

```
#include <linux/sched.h>
#include <linux/unistd.h>

pid_t clone(void *sp, unsigned long flags);
```

DESCRIPTION

clone is an alternate interface to fork, with more options. fork is equivalent to clone(0, SIGCLD|COPYVM).

If sp is nonzero, the child process uses sp as its initial stack pointer.

The low byte of flags contains the signal sent to the parent when the child dies. flags may also be bitwise ored with either or both of COPYVM and COPYFD.

If COPYVM is set, child pages are copy-on-write images of the parent pages. If COPYVM is not set, the child process shares the same pages as the parent, and both parent and child may write on the same data.

If COPYFD is set, the child's file descriptors are copies of the parent's file descriptors. If COPYFD is not set, the child's file descriptors are shared with the parent.

RETURN VALUE

On success, the PID of the child process is returned in the parent's thread of execution, and 0 is returned in the child's thread of execution. On failure, a -1 will be returned in the parent's context, no child process will be created, and errno will be set appropriately.

ERRORS

ENOSYS	clone will always return this error, unless your kernel was compiled with CLONE_ACTUALLY_WORKS_OK defined.
EAGAIN	fork cannot allocate sufficient memory to copy the parent's page tables and allocate a task structure for the child.

BUGS

By default, CLONE_ACTUALLY_WORKS_OK is not defined.

There is no entry for clone in /lib/libc.so.4.5.26.

Comments in the kernel as of 1.1.46 indicate that it mishandles the case where COPYVM is not set.

SEE ALSO

fork(2)

Linux 1.2.9, 10 June 1995

close

`close`—Closes a file descriptor

SYNOPSIS

```
#include <unistd.h>
int close(int fd);
```

DESCRIPTION

`close` closes a file descriptor so that it no longer refers to any file and may be reused. Any locks held on the file it was associated with, and owned by the process, are removed (regardless of the file descriptor that was used to obtain the lock).

If `fd` is the last copy of a particular file descriptor, the resources associated with it are freed; if the descriptor was the last reference to a file that has been removed using `unlink`, the file is deleted.

RETURN VALUE

`close` returns 0 on success, or -1 if an error occurred.

ERRORS

`EBADF` `fd` isn't a valid open file descriptor.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

NOTES

Not checking the return value of `close` is a common but nevertheless serious programming error. File system implementations that use techniques as write-behind to increase performance may lead to `write(2)` succeeding, although the data has not been written yet. The error status may be reported at a later write operation, but it is guaranteed to be reported on closing the file. Not checking the return value when closing the file may lead to silent loss of data. This can especially be observed with NFS and disk quotas.

connect

`connect`—Initiates a connection on a socket

SYNOPSIS

```
#include <sys/types.h>
#include <sys/socket.h>
int connect(int sockfd, struct sockaddr *serv_addr, int addrlen);
```

DESCRIPTION

The parameter `sockfd` is a socket. If it is of type `SOCK_DGRAM`, this call specifies the peer with which the socket is to be associated; this address is that to which datagrams are to be sent, and the only address from which datagrams are to be received. If the socket is of type `SOCK_STREAM`, this call attempts to make a connection to another socket. The other socket is

specified by `serv_addr`, which is an address in the communications space of the socket. Each communications space interprets the `serv_addr` parameter in its own way. Generally, stream sockets may successfully connect only once; datagram sockets may use `connect` multiple times to change their association. Datagram sockets may dissolve the association by connecting to an invalid address, such as a null address.

RETURN VALUE

If the connection or binding succeeds, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

See the Linux kernel source code for details.

HISTORY

The `connect` function call first appeared in BSD 4.2.

SEE ALSO

Linux 0.99.11, 23 July 1993

dup, dup2

`dup`, `dup2`—Duplicate a file descriptor

SYNOPSIS

```
#include <unistd.h>
int dup(int oldfd);
int dup2(int oldfd, intnewfd);
```

DESCRIPTION

`dup` and `dup2` create a copy of the file descriptor `oldfd`.

The old and new descriptors can be used interchangeably. They share locks, file position pointers and flags; for example, if the file position is modified by using `lseek` on one of the descriptors, the position is also changed for the other.

The two descriptors do not share the close-on-exec flag, however.

`dup` uses the lowest-numbered unused descriptor for the new descriptor.

`dup2` makes `newfd` be the copy of `oldfd`, closing `newfd` first if necessary.

RETURN VALUE

`dup` and `dup2` return the new descriptor, or `-1` if an error occurred (in which case `errno` is set appropriately).

ERRORS

<code>EBADF</code>	<code>oldfd</code> isn't an open file descriptor, or <code>newfd</code> is out of the allowed range for file descriptors.
<code>EMFILE</code>	The process already has the maximum number of file descriptors open and tried to open a new one.

WARNING

The error returned by `dup2` is different from that returned by `fcntl(..., F_DUPFD, ...)` when `newfd` is out of range. On some systems `dup2` also sometimes returns `EINVAL` like `F_DUPFD`.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

SEE ALSO

`fcntl(2)`, `open(2)`, `close(2)`.

execve

`execve`—Execute program

SYNOPSIS

```
#include <unistd.h>
int execve (const char *filename, const char *argv [], const char *envp[]);
```

DESCRIPTION

`execve()` executes the program pointed to by `filename`. `filename` must be either a binary executable or a shell script starting with a line in the format `#! interpreter [arg]`.

`execve()` does not return on success, and the text, data, bss, and stack of the calling process are overwritten by that of the program loaded. The program invoked inherits the calling process's PID, and any open file descriptors that are not set to close on exec. Signals pending on the parent process are cleared.

If the current program is being `ptraced`, a `SIGTRAP` is sent to it after a successful `execve()`.

RETURN VALUE

On success, `execve()` does not return; on error `-1` is returned and `errno` is set appropriately.

ERRORS

<code>EACCES</code>	The file is not a regular file.
<code>EACCES</code>	Execute permission is denied for the file.
<code>EPERM</code>	The file system is mounted <code>noexec</code> .
<code>EPERM</code>	The file system is mounted <code>nosuid</code> and the file has an SUID or SGID bit set.
<code>E2BIG</code>	The argument list is too big.
<code>ENOEXEC</code>	The magic number in the file is incorrect.
<code>EFAULT</code>	<code>filename</code> points outside your accessible address space.
<code>ENAMETOOLONG</code>	<code>filename</code> is too long.
<code>ENOENT</code>	The file does not exist.
<code>ENOMEM</code>	Insufficient kernel memory was available.
<code>ENOTDIR</code>	A component of the path prefix is not a directory.
<code>EACCES</code>	Search permission is denied on a component of the path prefix.
<code>ELOOP</code>	<code>filename</code> contains a circular reference (that is, via a symbolic link).

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

NOTES

SUID and SGID processes can not be `ptrace()`'d SUID or SGID.

A maximum line length of 127 characters is allowed for the first line in a `#!` executable shell script. This may be circumvented by changing the `max` size of `buf`, in which case you will become bound by the 1024 byte size of a buffer, which is not easily worked around.

fcntl

fcntl—Manipulate file descriptor

SYNOPSIS

```
#include <unistd.h>
#include <fcntl.h>
int fcntl(int fd,intcmd);
int fcntl(int fd,intcmd,longarg);
```

DESCRIPTION

`fcntl` performs one of various miscellaneous operations on `fd`. The operation in question is determined by `cmd`:

<code>F_DUPFD</code>	Makes <code>arg</code> be a copy of <code>fd</code> , closing <code>fd</code> first if necessary. The same functionality can be more easily achieved by using <code>dup2(2)</code> . The old and new descriptors may be used interchangeably. They share locks, file position pointers, and flags; for example, if the file position is modified by using <code>lseek</code> on one of the descriptors, the position is also changed for the other. The two descriptors do not share the close-on-exec flag, however. On success, the new descriptor is returned.
<code>F_GETFD</code>	Read the close-on-exec flag. If the low-order bit is 0, the file will remain open across <code>exec</code> ; otherwise, it will be closed.
<code>F_SETFD</code>	Set the close-on-exec flag to the value specified by <code>arg</code> (only the least significant bit is used).
<code>F_GETFL</code>	Read the descriptor's flags (all flags—as set by <code>open(2)</code> —are returned).
<code>F_SETFL</code>	Set the descriptor's flags to the value specified by <code>arg</code> . Only <code>O_APPEND</code> and <code>O_NONBLOCK</code> may be set. The flags are shared between copies (made with <code>dup</code> and so on) of the same file descriptor. The flags and their semantics are described in <code>open(2)</code> .
<code>F_GETLK</code> , <code>F_SETLK</code> , and <code>F_SETLKW</code>	Manage discretionary file locks. The third argument <code>arg</code> is a pointer to a struct <code>flock</code> (that may be overwritten by this call).
<code>F_GETLK</code>	Return the <code>flock</code> structure that prevents us from obtaining the lock, or set the <code>l_type</code> field of the lock to <code>F_UNLCK</code> if there is no obstruction.
<code>F_SETLK</code>	The lock is set (when <code>l_type</code> is <code>F_RDLOCK</code> or <code>F_WRLCK</code>) or cleared (when it is <code>F_UNLCK</code>). If the lock is held by someone else, this call returns <code>-1</code> and sets <code>errno</code> to <code>EACCES</code> or <code>EAGAIN</code> .
<code>F_SETLKW</code>	Like <code>F_SETLK</code> , but instead of returning an error, we wait for the lock to be released.
<code>F_GETOWN</code>	Get the process ID (or process group) of the owner of a socket. Process groups are returned as negative values.
<code>F_SETOWN</code>	Set the process or process group that owns a socket. For these commands, ownership means receiving <code>SIGIO</code> or <code>SIGURG</code> signals. Process groups are specified using negative values.

RETURN VALUE

The return value depends on the operation:

F_DUPFD	The new descriptor.
F_GETFD	Value of flag.
F_GETFL	Value of flags.
F_GETOWN	Value of descriptor owner.

On error, `-1` is returned and `errno` is set appropriately.

ERRORS

EBADF	<code>fd</code> is not an open file descriptor.
EINVAL	For F_DUPFD, <code>arg</code> is negative or is greater than the maximum allowable value.
EMFILE	For F_DUPFD, the process already has the maximum number of file descriptors open.

NOTES

The errors returned by `dup2` are different from those returned by F_DUPFD.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

fdatasync

`fdatasync`—Synchronizes a file's in-core data with that on disk

SYNOPSIS

```
#include <unistd.h>
#ifdef POSIX SYNCHRONIZED IO
int fdatasync(int fd);
#endif
```

DESCRIPTION

`fdatasync` flushes all data buffers of a file to disk (before the system call returns). It resembles `fsync` but is not required to update the metadata such as access time.

Applications that access databases or log files often write a tiny data fragment (for example, one line in a log file) and then call `fsync` immediately in order to ensure that the written data is physically stored on the hard disk. Unfortunately, `fsync` will always initiate two write operations: one for the newly written data and another one in order to update the modification time stored in the inode. If the modification time is not a part of the transaction concept `fdatasync` can be used to avoid unnecessary inode disk write operations.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

EBADF	<code>fd</code> is not a valid file descriptor open for writing.
EROFS, EINVAL	<code>fd</code> is bound to a special file which does not support synchronization.
EIO	An error occurred during synchronization.

BUGS

Currently (Linux 1.3.86) `fdatasync` is equivalent to `fsync`.

CONFORMS TO

POSIX.4

`fsync(2)`, B.O. Gallmeister, *POSIX.4*, O'Reilly, pp. 220–223, 343.

Linux 1.3.86, 13 April 1996

flock

`flock`—Applies or removes an advisory lock on an open file

SYNOPSIS

```
#include <sys/file.h>
int flock(int fd,intoperation);
```

DESCRIPTION

Apply or remove an advisory lock on an open file. The file is specified by `fd`. Valid operations are given here:

LOCK_SH	Shared lock. More than one process may hold a shared lock for a given file at a given time.
LOCK_EX	Exclusive lock. Only one process may hold an exclusive lock for a given file at a given time.
LOCK_UN	Unlock.
LOCK_NB	Don't block when locking. May be specified (by oring) along with one of the other operations. A single file may not have both shared and exclusive locks. A file is locked (that is, the inode), <i>not</i> the file descriptor. So, <code>dup(2)</code> and <code>fork(2)</code> do not create multiple instances of a lock.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

EWOULDBLOCK	The file is locked and the <code>LOCK_NB</code> flag was selected.
-------------	--

NOTES

Under Linux, `flock` is implemented as a call to `fcntl`. Please see `fcntl(2)` for more details on errors.

Linux 0.99.11, 22 July 1993

fork, vfork

fork, vfork—Creates a child process

SYNOPSIS

```
#include <unistd.h>
pid_t fork(void);
pid_t vfork(void);
```

DESCRIPTION

fork creates a child process that differs from the parent process only in its PID and PPID, and in the fact that resource utilizations are set to 0. File locks and pending signals are not inherited.

Under Linux, fork is implemented using copy-on-write pages, so the only penalties incurred by fork are the time and memory required to duplicate the parent's page tables and to create a unique task structure for the child.

RETURN VALUE

On success, the PID of the child process is returned in the parent's thread of execution, and a 0 is returned in the child's thread of execution. On failure, a -1 will be returned in the parent's context, no child process will be created, and errno will be set appropriately.

ERRORS

EAGAIN fork cannot allocate sufficient memory to copy the parent's page tables and allocate a task structure for the child.

BUGS

Under Linux, vfork is merely an alias for fork. fork never returns the error ENOMEM.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

Linux 1.2.9, 10 June 1995

fsync

fsync—Synchronizes a file's complete in-core state with that on disk

SYNOPSIS

```
#include <unistd.h>
int fsync(int fd);
```

DESCRIPTION

fsync copies all in-core parts of a file to disk.

In some applications, fdatsync is a more efficient alternative to fsync.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and errno is set appropriately.

ERRORS

EBADF	<code>fd</code> is not a valid file descriptor open for writing.
EROFS, EINVAL	<code>fd</code> is bound to a special file that does not support synchronization.
EIO	An error occurred during synchronization.

CONFORMS TO

POSIX.1b

SEE ALSO

Linux 1.3.85, 13 April 1996

getdents

getdents—Gets directory entries

SYNOPSIS

```
#include <unistd.h>
#include <linux/dirent.h>
#include <linux/unistd.h>
syscall3(int, getdents, uint, fd, struct dirent *, dirp, uint, count);
int getdents(unsigned int fd, struct dirent *dirp, unsigned int count);
```

DESCRIPTION

`getdents` reads several `dirent` structures from the directory pointed at by `fd` into the memory area pointed to by `dirp`. The parameter `count` is the size of the memory area.

The `dirent` structure is declared as follows:

```
struct dirent
{
    long d_ino;           /* inode number */
    off_t d_off;         /* offset to next dirent */
    unsigned short d_reclen; /* length of this dirent */
    char d_name [NAME_MAX+1]; /* file name (null-terminated) */
}
```

`d_ino` is an inode number. `d_off` is the distance from the start of the directory to the start of the next `dirent`. `d_reclen` is the size of this entire *dirent*. `d_name` is a null-terminated filename.

This call supersedes `readdir(2)`.

RETURN VALUE

On success, the number of bytes read is returned. On end of directory, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

EBADF	Invalid file descriptor <code>fd</code> .
ENOTDIR	File descriptor does not refer to a directory.

SEE ALSO

readdir(2), readdir(3)

Linux 1.3.6, 22 July 1995

getdomainname, setdomainname

getdomainname, setdomainname—Gets/sets domain name

SYNOPSIS

```
#include <unistd.h>
int getdomainname(char *name, size_t len);
int setdomainname(const char *name, size_t len);
```

DESCRIPTION

These functions are used to access or to change the domain name of the current processor.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

EINVAL	For <code>getdomainname</code> , <code>name</code> points to NULL or <code>name</code> is longer than <code>len</code> .
EPERM	For <code>setdomainname</code> , the caller was not the superuser.
EINVAL	For <code>setdomainname</code> , <code>len</code> was too long.

CONFORMS TO

POSIX does not specify these calls.

BUGS

`getdomainname` is not compliant with other implementations because they always return `len` bytes, even if `name` is longer. Linux, however, returns `EINVAL` in this case (as of DLL 4.4.1 libraries).

NOTES

Under Linux, `getdomainname` is implemented at the library level by calling `uname(2)`.

Linux 0.99.11, 22 July 1993

getdtablesize

getdtablesize—Gets descriptor table size

SYNOPSIS

```
#include <unistd.h>
int getdtablesize(void);
```

DESCRIPTION

`getdtablesize` returns the maximum number of files a process can have open.

NOTES

`getdtablesize` is implemented as a library function in DLL 4.4.1. This function returns `OPEN_MAX` (set to 256 in Linux 0.99.11) if `OPEN_MAX` was defined when the library was compiled. Otherwise, -1 is returned and `errno` is set to `ENOSYS`.

SEE ALSO

`close(2)`, `dup(2)`, `open(2)`*Linux 0.99.11, 22 July 1993*

getgid, getegid

getgid, getegid—Gets group identity

SYNOPSIS

```
#include <unistd.h>
gid_t getgid(void);
gid_t getegid(void);
```

DESCRIPTION

`getgid` returns the real group ID of the current process.`getegid` returns the effective group ID of the current process.

The real ID corresponds to the ID of the calling process. The effective ID corresponds to the set ID bit on the file being executed.

ERRORS

These functions are always successful.

CONFORMS TO

POSIX, BSD 4.3

SEE ALSO

`setregid(2)`, `setgid(2)`*Linux 0.99.11, 23 July 1993*

getgroups, setgroups

getgroups, setgroups—Gets/sets group access list

SYNOPSIS

```
#include <unistd.h>
int getgroups(int size, gid_t list[]);
#define USE_BSD
#include <grp.h>
int setgroups(size_t size, const gid_t *list);
```

DESCRIPTION

`getgroups`

Up to `size` supplemental groups are returned in `list`. If `size` is 0, `list` is not modified, but the total number of supplemental groups for the process is returned.

`setgroups`

Sets the supplemental groups for the process. Only the superuser may use this function.

RETURN VALUE

<code>getgroups</code>	On success, the number of groups stored in <i>list</i> is returned (if <code>size</code> is 0, however, the number of supplemental group IDs associated with the process is returned). On error, <code>-1</code> is returned and <code>errno</code> is set appropriately.
<code>setgroups</code>	On success, <code>0</code> is returned. On error, <code>-1</code> is returned and <code>errno</code> is set appropriately.

ERRORS

<code>EFAULT</code>	<code>list</code> has an invalid address.
<code>EPERM</code>	For <code>setgroups</code> , the user is not the superuser.
<code>EINVAL</code>	For <code>setgroups</code> , <code>gidsetsize</code> is greater than <code>NGROUPS</code> (32 for Linux 0.99.11).

CONFORMS TO

`getgroups` conforms to POSIX.1 (and is present in BSD 4.3). Since `setgroups` requires privilege, it is not covered under POSIX.1.

BUGS

The `USE BSD` flag probably shouldn't be required for `setgroups`.

SEE ALSO

`initgroups(3)`

Linux 0.99.11, 23 July 1993

gethostid, sethostid

`gethostid`, `sethostid`—Gets/sets the unique identifier of the current host

SYNOPSIS

```
#include <unistd.h>

long int gethostid(void);
int sethostid(long int hostid);
```

DESCRIPTION

Get or set a unique 32-bit identifier for the current machine. The 32-bit identifier is intended to be unique among all UNIX systems in existence. This normally resembles the Internet address for the local machine, as returned by `gethostbyname(3)`, and thus usually never needs to be set.

The `sethostid` call is restricted to the superuser.

The `hostid` argument is stored in the file `/etc/hostid`.

RETURN VALUES

`gethostid` returns the 32-bit identifier for the current host as set by `sethostid(2)`.

CONFORMS TO

POSIX.1 does not define these functions, but ISO/IEC 9945-1:1990 mentions them in B.4.4.1.

FILES

`/etc/hostid`

SEE ALSO

hostid(1), gethostbyname(3)

Linux 0.99.13, 29 November 1993

gethostname, sethostname

gethostname, sethostname—Gets/sets hostname

SYNOPSIS

```
#include <unistd.h>
int gethostname(char *name, size_t len);
int sethostname(const char *name, size_t len);
```

DESCRIPTION

These functions are used to access or to change the hostname of the current processor.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

EINVAL	<code>len</code> is negative or, for <code>sethostname</code> , larger than the maximum allowed size. For <code>gethostname</code> on Linux/i386, <code>len</code> is smaller than the actual size.
EPERM	For <code>sethostname</code> , the caller was not the superuser.
EFAULT	<code>name</code> is an invalid address.

CONFORMS TO

POSIX.1 does not define these functions, but ISO/IEC 9945-1:1990 mentions them in B.4.4.1.

BUGS

Some other implementations of `gethostname` successfully return `len` bytes even if `name` is longer. Linux/Alpha complies with this behavior. Linux/i386, however, returns `EINVAL` in this case (as of DLL 4.6.27 libraries).

NOTES

Under Linux/Alpha, `gethostname` is a system call. Under Linux/i386, `gethostname` is implemented at the library level by calling `uname(2)`.

SEE ALSO

getdomainname(2), setdomainname(2), uname(2)

Linux 1.3.6, 22 July 1995

getitimer, setitimer

getitimer, setitimer—Gets/sets value of an interval timer

SYNOPSIS

```
#include <sys/time.h>
int getitimer(int which, struct itimerval *value);
int setitimer(int which, const struct itimerval *value, struct itimerval *ovalue);
```

DESCRIPTION

The system provides each process with three interval timers, each decrementing in a distinct time domain. When any timer expires, a signal is sent to the process, and the timer (potentially) restarts.

ITIMER_REAL	Decrements in real time and delivers SIGALRM upon expiration.
ITIMER_VIRTUAL	Decrements only when the process is executing, and delivers SIGVTALRM upon expiration.
ITIMER_PROF	Decrements both when the process executes and when the system is executing on behalf of the process. Coupled with ITIMER_VIRTUAL, this timer is usually used to profile the time spent by the application in user and kernel space. SIGPROF is delivered upon expiration.

Timer values are defined by the following structures:

```
struct itimerval {
    struct timeval it_interval; /* next value */
    struct timeval it_value;   /* current value */
};
struct timeval {
    long tv_sec;              /* seconds */
    long tv_usec;            /* microseconds */
};
```

`getitimer(2)` fills the structure indicated by `value` with the current setting for the timer indicated by `which` (one of ITIMER_REAL, ITIMER_VIRTUAL, or ITIMER_PROF). The element `it_value` is set to the amount of time remaining on the timer, or 0 if the timer is disabled. Similarly, `it_interval` is set to the reset value. `setitimer(2)` sets the indicated timer to the value in `value`. If `ovalue` is nonzero, the old value of the timer is stored there.

Timers decrement from `it_value` to 0, generate a signal, and reset to `it_interval`. A timer that is set to 0 (`it_value` is 0 or the timer expires and `it_interval` is 0) stops.

Both `tv_sec` and `tv_usec` are significant in determining the duration of a timer.

Timers will never expire before the requested time, instead expiring some short, constant time afterward, dependent on the system timer resolution (currently 10ms). Upon expiration, a signal will be generated and the timer reset. If the timer expires while the process is active (always true for ITIMER_VIRT), the signal will be delivered immediately when generated. Otherwise, the delivery will be offset by a small time dependent on the system loading.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

EFAULT	<code>value</code> and <code>ovalue</code> are not valid pointers.
EINVAL	<code>which</code> is not one of ITIMER_REAL, ITIMER_VIRT, or ITIMER_PROF.

SEE ALSO

`gettimeofday(2)`, `sigaction(2)`, `signal(2)`

BUGS

Under Linux, the generation and delivery of a signal are distinct and there each signal is permitted only one outstanding event. It's therefore conceivable that under pathologically heavy loading, ITIMER_REAL will expire before the signal from a previous expiration has been delivered. The second signal in such an event will be lost.

Linux 0.99.11, 5 August 1993

getpagesize

getpagesize—Gets system page size

SYNOPSIS

```
#include <unistd.h>
size_t getpagesize(void);
```

DESCRIPTION

Returns the number of bytes in a page. This is the system's page size, which is not necessarily the same as the hardware page size.

NOTES

getpagesize is implemented as a library function in DLL 4.4.1. Depending on what is defined when the library is compiled, this function returns EXEC_PAGESIZE (set to 4096 in Linux 0.99.11), NBPG (set to 4096 in Linux 0.99.11), or NBPC (not defined in Linux 0.99.11 or DLL 4.4.1 libraries).

SEE ALSO

sbrk(2)

Linux 0.99.11, 23 July 1993

getpeername

getpeername—Gets the name of the connected peer

SYNOPSIS

```
int getpeername(int s, struct sockaddr *name, int*namelen);
```

DESCRIPTION

getpeername returns the name of the peer connected to socket *s*. The *namelen* parameter should be initialized to indicate the amount of space pointed to by *name*. On return it contains the actual size of the name returned (in bytes). The name is truncated if the buffer provided is too small.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and *errno* is set appropriately.

ERRORS

EADDR	The argument <i>s</i> is not a valid descriptor.
ENOTSOCK	The argument <i>s</i> is a file, not a socket.
ENOTCONN	The socket is not connected.
ENOBUFS	Insufficient resources were available in the system to perform the operation.
EFAULT	The <i>name</i> parameter points to memory not in a valid part of the process address space.

HISTORY

The `getpeername` function call appeared in BSD 4.2.

SEE ALSO

accept(2), bind(2), getsockname(2)

BSD Man Page, 24 July 1993

getpid, getppid

getpid, getppid—Gets process identification

SYNOPSIS

```
#include <unistd.h>
pid_t getpid(void);
pid_t getppid(void);
```

DESCRIPTION

getpid returns the process ID of the current process. (This is often used by routines that generate unique temporary filenames.)

getppid returns the process ID of the parent of the current process.

CONFORMS TO

POSIX, BSD 4.3, SVID

SEE ALSO

exec(2), fork(2), kill(2), mkstemp(3), tmpnam(3), tempnam(3), tmpfile(3)

Linux 0.99.11, 23 July 1993

getpriority, setpriority

getpriority, setpriority—Gets/sets program scheduling priority

SYNOPSIS

```
#include <sys/time.h>
#include <sys/resource.h>
int getpriority(int which,int who);
int setpriority(int which,int who,int prio);
```

DESCRIPTION

The scheduling priority of the process, process group, or user, as indicated by `which` and `who`, is obtained with the `getpriority` call and set with the `setpriority` call. `which` is one of `PRIO_PROCESS`, `PRIO_PGRP`, or `PRIO_USER`, and `who` is interpreted relative to `which` (a process identifier for `PRIO_PROCESS`, process group identifier for `PRIO_PGRP`, and a user ID for `PRIO_USER`). A `0` value of `who` denotes the current process, process group, or user. `prio` is a value in the range `-20` to `20`. The default priority is `0`; lower priorities cause more favorable scheduling.

The `getpriority` call returns the highest priority (lowest numerical value) enjoyed by any of the specified processes. The `setpriority` call sets the priorities of all the specified processes to the specified value. Only the superuser may lower priorities.

RETURN VALUES

Because `getpriority` can legitimately return the value `-1`, it is necessary to clear the external variable `errno` prior to the call, and then check it afterward to determine whether a `-1` is an error or a legitimate value. The `setpriority` call returns `0` if there is no error, or `-1` if there is.

ERRORS

ESRCH	No process was located using the <code>which</code> and <code>who</code> values specified.
EINVAL	<code>which</code> was not one of <code>PRIO_PROCESS</code> , <code>PRIO_PGRP</code> , or <code>PRIO_USER</code> .

In addition to these errors, `setpriority` will fail with the following:

EPERM	A process was located, but neither its effective nor real user ID matched the effective user ID of the caller.
EACCES	A nonsuperuser attempted to lower a process priority.

HISTORY

These function calls appeared in BSD 4.2.

SEE ALSO

`nice(1)`, `fork(2)`, `renice(8)`

BSD Man Page, 24 July 1993

getrlimit, getrusage, setrlimit

getrlimit, getrusage, setrlimit—Get/set resource limits and usage

SYNOPSIS

```
#include <sys/time.h>
#include <sys/resource.h>
#include <unistd.h>

int getrlimit (int resource, struct rlimit *rlim);
int getrusage (int who, struct rusage *usage);
int setrlimit (int resource, const struct rlimit *rlim);
```

DESCRIPTION

`getrlimit` and `setrlimit` get and set resource limits. `resource` should be one of the following:

```
RLIMIT CPU /* CPU time in seconds */
RLIMIT FSIZE /* Maximum filesize */
RLIMIT DATA /* max data size */
RLIMIT STACK /* max stack size */
RLIMIT CORE /* max core file size */
RLIMIT RSS /* max resident set size */
RLIMIT NPROC /* max number of processes */
RLIMIT NOFILE /* max number of open files */
RLIMIT MEMLOCK /* max locked-in-memory address space*/
```

A resource may be unlimited if you set the limit to `RLIM_INFINITY`. `RLIMIT_NOFILE` is the BSD name for `RLIMIT_NOFILE`.

The `rlimit` structure is defined as follows :

```
struct rlimit
{
    int rlim_cur;
    int rlim_max;
};
```

`getrusage` returns the current resource usages for a `who` of either `RUSAGE_SELF` or `RUSAGE_CHILDREN`:

```
struct rusage
{
    struct timeval ru_utime; /* user time used */
    struct timeval ru_stime; /* system time used */
    long ru_maxrss; /* maximum resident set size */
    long ru_ixrss; /* integral shared memory size */
```

```

    long ru_idrss;           /* integral unshared data size */
    long ru_isrss;         /* integral unshared stack size */
    long ru_minflt;        /* page reclaims */
    long ru_majflt;        /* page faults */
    long ru_nswap;         /* swaps */
    long ru_inblock;       /* block input operations */
    long ru_oublock;       /* block output operations */
    long ru_msgsnd;        /* messages sent */
    long ru_msgrcv;        /* messages received */
    long ru_nsignals;      /* signals received */
    long ru_nvcsw;         /* voluntary context switches */
    long ru_nivcsw;        /* involuntary context switches */
};

```

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

`EINVAL` `getrlimit` or `setrlimit` is called with a bad resource. `getrusage` is called with a bad who.
`EPERM` A nonsuperuser tries to use `setrlimit()` to increase the soft or hard limit above the current hard limit, or a superuser tries to increase `RLIMIT_NOFILE` above the current kernel maximum.

CONFORMS TO

BSD 4.3

getsid

`getsid`—Gets session ID

SYNOPSIS

```

#include <unistd.h>
pid_t getsid(void);

```

DESCRIPTION

`getsid(0)` returns the session ID of the calling process. `getsid(p)` returns the session ID of the process with process ID `p`.

ERRORS

On error, -1 will be returned. The only error that can happen is `ESRCH`, when no process with process ID `p` was found.

CONFORMS TO

This call is Linux specific.

SEE ALSO

`setsid(2)`

Linux 1.3.85, 11 April 1996

getsockname

getsockname—Gets socket name

SYNOPSIS

```
int getsockname(int s ", struct sockaddr *" name ", int *" namelen );
```

DESCRIPTION

`getsockname` returns the current `name` for the specified socket. The `namelen` parameter should be initialized to indicate the amount of space pointed to by `name`. On return it contains the actual size of the name returned (in bytes).

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

EBAADF	The argument <code>s</code> is not a valid descriptor.
ENOTSOCK	The argument <code>s</code> is a file, not a socket.
ENOBUFS	Insufficient resources were available in the system to perform the operation.
EFAULT	The <code>name</code> parameter points to memory not in a valid part of the process address space.

HISTORY

The `getsockname` function call appeared in BSD 4.2.

BUGS

Names bound to sockets in the UNIX domain are inaccessible; `getsockname` returns a 0-length name.

SEE ALSO

`bind(2)`, `socket(2)`

getsockopt, setsockopt

getsockopt, setsockopt—Get and set options on sockets

SYNOPSIS

```
#include <sys/types.h>
#include <sys/socket.h>
int getsockopt(int s,intlevel ,intoptname,void*optval ,int*optlen);
int setsockopt(int s,intlevel ,intoptname, const void *optval ,intoptlen);
```

DESCRIPTION

`getsockopt` and `setsockopt` manipulate the options associated with a socket. Options may exist at multiple protocol levels; they are always present at the uppermost socket level.

When manipulating socket options, the level at which the option resides and the name of the option must be specified. To manipulate options at the socket level, `level` is specified as `SOL_SOCKET`. To manipulate options at any other level, the protocol number of the appropriate protocol controlling the option is supplied. For example, to indicate that an option is to be interpreted by the TCP protocol, `level` should be set to the protocol number of TCP; see `getprotoent(3)`.

The parameters `optval` and `optlen` are used to access option values for `setsockopt`. For `getsockopt` they identify a buffer in which the value for the requested option(s) is to be returned. For `getsockopt`, `optlen` is a value-result parameter, initially containing the size of the buffer pointed to by `optval`, and modified on return to indicate the actual size of the value returned. If no option value is to be supplied or returned, `optval` may be `NULL`.

`optname` and any specified options are passed uninterpreted to the appropriate protocol module for interpretation. The include file `<sys/socket.h>` contains definitions for socket-level options, described below. Options at other protocol levels vary in format and name; consult the appropriate entries in section 4 of the manual.

Most socket-level options utilize an `int` parameter for `optval`. For `setsockopt`, the parameter should be nonzero to enable a boolean option, or 0 if the option is to be disabled. `SO_LINGER` uses a `struct linger` parameter, defined in `<linux/socket.h>`, which specifies the desired state of the option and the linger interval (see below). `SO_SNDTIMEO` and `SO_RCVTIMEO` use a `struct timeval` parameter, defined in `<sys/time.h>`.

The following options are recognized at the socket level. Except as noted, each may be examined with `getsockopt` and set with `setsockopt`:

<code>SO_DEBUG</code>	Enables recording of debugging information.
<code>SO_REUSEADDR</code>	Enables local address reuse.
<code>SO_KEEPALIVE</code>	Enables keep connections alive.
<code>SO_DONTRROUTE</code>	Enables routing bypass for outgoing messages.
<code>SO_LINGER</code>	Linger on close if data present.
<code>SO_BROADCAST</code>	Enables permission to transmit broadcast messages.
<code>SO_OOBINLINE</code>	Enables reception of out-of-band data in band.
<code>SO_SNDBUF</code>	Sets buffer size for output.
<code>SO_RCVBUF</code>	Sets buffer size for input.
<code>SO_SNDLOWAT</code>	Sets minimum count for output.
<code>SO_RCVLOWAT</code>	Sets minimum count for input.
<code>SO_SNDTIMEO</code>	Sets time-out value for output.
<code>SO_RCVTIMEO</code>	Sets time-out value for input.
<code>SO_TYPE</code>	Gets the type of the socket (get only).
<code>SO_ERROR</code>	Gets and clears error on the socket (get only).

`SO_DEBUG` enables debugging in the underlying protocol modules.

`SO_REUSEADDR` indicates that the rules used in validating addresses supplied in a `bind(2)` call should allow reuse of local addresses.

`SO_KEEPALIVE` enables the periodic transmission of messages on a connected socket. Should the connected party fail to respond to these messages, the connection is considered broken and processes using the socket are notified via a `SIGPIPE` signal when attempting to send data.

`SO_DONTRROUTE` indicates that outgoing messages should bypass the standard routing facilities. Instead, messages are directed to the appropriate network interface according to the network portion of the destination address.

`SO_LINGER` controls the action taken when unsent messages are queued on socket and a `close(2)` is performed. If the socket promises reliable delivery of data and `SO_LINGER` is set, the system will block the process on the close attempt until it is able to transmit the data or until it decides it is unable to deliver the information (a time-out period, termed the linger interval, is specified in the `setsockopt` call when `SO_LINGER` is requested). If `SO_LINGER` is disabled and a close is issued, the system will process the close in a manner that allows the process to continue as quickly as possible.

The `linger` structure is defined in `<linux/socket.h>` as follows:

```
struct linger {
    int l_onoff; /* Linger active */
    int l_linger; /* How long to linger for */
};
```

`l_onoff` indicates whether to linger. If it is set to 1, `l_linger` contains the time in hundredths of seconds how long the process should linger to complete the close. If `l_onoff` is set to 0, the process returns immediately.

The option `SO_BROADCAST` requests permission to send broadcast datagrams on the socket. Broadcast was a privileged operation in earlier versions of the system. With protocols that support out-of-band data, the `SO_OOBINLINE` option requests that out-of-band data be placed in the normal data input queue as received; it will then be accessible with `recv` or `read` calls without the `MSG_OOB` flag. Some protocols always behave as if this option is set.

`SO_SNDBUF` and `SO_RCVBUF` are options to adjust the normal buffer sizes allocated for output and input buffers, respectively. The buffer size may be increased for high-volume connections or may be decreased to limit the possible backlog of incoming data. The system places an absolute limit on these values.

`SO_SNDLOWAT` is an option to set the minimum count for output operations. Most output operations process all of the data supplied by the call, delivering data to the protocol for transmission and blocking as necessary for flow control. Nonblocking output operations will process as much data as permitted subject to flow control without blocking, but will process no data if flow control does not allow the smaller of the low water mark value or the entire request to be processed. A `select(2)` operation testing the ability to write to a socket will return true only if the low water mark amount could be processed. The default value for `SO_SNDLOWAT` is set to a convenient size for network efficiency, often 1024.

`SO_RCVLOWAT` is an option to set the minimum count for input operations. In general, receive calls will block until any (nonzero) amount of data is received, then return with the smaller of the amount available or the amount requested. The default value for `SO_RCVLOWAT` is 1. If `SO_RCVLOWAT` is set to a larger value, blocking receive calls normally wait until they have received the smaller of the low water mark value or the requested amount. Receive calls may still return less than the low water mark if an error occurs, a signal is caught, or the type of data next in the receive queue is different than that returned.

`SO_SNDTIMEO` is an option to set a time-out value for output operations. It accepts a `struct timeval` parameter with the number of seconds and microseconds used to limit waits for output operations to complete. If a send operation has blocked for this much time, it returns with a partial count or with the error `EWOULDBLOCK` if no data were sent. In the current implementation, this timer is restarted each time additional data are delivered to the protocol, implying that the limit applies to output portions ranging in size from the low water mark to the high water mark for output.

`SO_RCVTIMEO` is an option to set a time-out value for input operations. It accepts a `struct timeval` parameter with the number of seconds and microseconds used to limit waits for input operations to complete. In the current implementation, this timer is restarted each time additional data are received by the protocol, and thus the limit is in effect an inactivity timer. If a receive operation has been blocked for this much time without receiving additional data, it returns with a short count or with the error `EWOULDBLOCK` if no data were received.

Finally, `SO_TYPE` and `SO_ERROR` are options used only with `setsockopt`.

`SO_TYPE` returns the type of the socket, such as `SOCK_STREAM`; it is useful for servers that inherit sockets on startup.

`SO_ERROR` returns any pending error on the socket and clears the error status. It may be used to check for asynchronous errors on connected datagram sockets or for other asynchronous errors.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

<code>EBAADF</code>	The argument <code>s</code> is not a valid descriptor.
<code>ENOTSOCK</code>	The argument <code>s</code> is a file, not a socket.
<code>ENOPROTOPT</code>	The option is unknown at the level indicated.
<code>EFAULT</code>	The address pointed to by <code>optval</code> is not in a valid part of the process address space. For <code>getsockopt</code> , this error may also be returned if <code>optlen</code> is not in a valid part of the process address space.

HISTORY

These system calls appeared in BSD 4.2.

BUGS

Several of the socket options should be handled at lower levels of the system.

gettimeofday, settimeofday

`gettimeofday`, `settimeofday`—Get/set time

SYNOPSIS

```
#include <sys/time.h>
#include <unistd.h>

int gettimeofday(struct timeval *tv, struct timezone *tz);
int settimeofday(const struct timeval *tv, const struct timezone *tz);
```

DESCRIPTION

`gettimeofday` and `settimeofday` can set the time as well as a time zone. `tv` is a `timeval` struct, as specified in `/usr/include/sys/time.h`:

```
struct timeval {
    long tv_sec;        /* seconds */
    long tv_usec;     /* microseconds */
};
```

and `tz` is a `timezone`:

```
struct timezone {
    int tz_minuteswest;
    /* minutes west of Greenwich */
    int tz_dsttime;
    /* type of dst correction */
};
```

with daylight savings times defined as follows:

```
DST_NONE    /* not on dst */
DST_USA     /* USA style dst */
DST_AUST    /* Australian style dst */
DST_WET     /* Western European dst */
DST_MET     /* Middle European dst */
DST_EET     /* Eastern European dst */
DST_CAN     /* Canada */
DST_GB      /* Great Britain and Eire */
DST_RUM     /* Rumania */
DST_TUR     /* Turkey */
DST_AUSTALT /* Australian style with shift in 1986 */
```

And the following macros are defined to operate on this :

```
#define timerisset(tvp)\
    ((tvp)->tv_sec || (tvp)->tv_usec)
#define timercmp(tvp, uvp, cmp)\
    ((tvp)->tv_sec cmp (uvp)->tv_sec ||\
    (tvp)->tv_sec == (uvp)->tv_sec &&\
    (tvp)->tv_usec cmp (uvp)->tv_usec)
#define timerclear(tvp)\
    ((tvp)->tv_sec = (tvp)->tv_usec = 0)
```

If either `tv` or `tz` is null, the corresponding structure is not set or returned.

Only the superuser can use `settimeofday`.

ERRORS

`EPERM` `settimeofday` is called by someone other than the superuser.
`EINVAL` Time zone (or something else) is invalid.

CONFORMS TO

BSD 4.3

getuid, geteuid

`getuid`, `geteuid`—Get user identity

SYNOPSIS

```
#include <unistd.h>
uid_t getuid(void);
uid_t geteuid(void);
```

DESCRIPTION

`getuid` returns the real user ID of the current process.

`geteuid` returns the effective user ID of the current process.

The real ID corresponds to the ID of the calling process. The effective ID corresponds to the set ID bit on the file being executed.

ERRORS

These functions are always successful.

CONFORMS TO

POSIX, BSD 4.3

SEE ALSO

Linux 0.99.11, 23 July 1993

idle

`idle`—Makes process 0 idle

SYNOPSIS

```
#include <unistd.h>
void idle(void);
```

DESCRIPTION

`idle` is an internal system call used during bootstrap. It marks the process's pages as swappable, lowers its priority, and enters the main scheduling loop. `idle` never returns.

Only process 0 may call `idle`. Any user process, even a process with superuser permission, will receive `EPERM`.

RETURN VALUE

`idle` never returns for process 0, and always returns `-1` for a user process.

ERRORS

`EPERM` Always, for a user process.

Linux 1.1.46, 21 August 1994

ioctl

`ioctl`—Controls devices

SYNOPSIS

```
#include <sys/ioctl.h>
int ioctl(int d,intrequest, ...);
```

(The “third” argument is traditionally `char *argp` and will be so named for this discussion.)

DESCRIPTION

The `ioctl` function manipulates the underlying device parameters of special files. In particular, many operating characteristics of character special files (for example, terminals) may be controlled with `ioctl` requests. The argument `d` must be an open file descriptor.

An `ioctl` request has encoded in it whether the argument is an `in` parameter or `out` parameter, and the size of the argument `argp` in bytes. Macros and defines used in specifying an `ioctl` request are located in the file `<sys/ioctl.h>`.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

<code>EBADF</code>	<code>d</code> is not a valid descriptor.
<code>ENOTTY</code>	<code>d</code> is not associated with a character special device.
<code>ENOTTY</code>	The specified request does not apply to the kind of object that the descriptor <code>d</code> references.
<code>EINVAL</code>	request or <code>argp</code> is not valid.

HISTORY

An `ioctl` function call appeared in version 7 AT&T UNIX.

SEE ALSO

execve(2), fcntl(2), mt(4), sd(4), tty(4)

INTRODUCTION

This is *ioctl* List 1.3.27, a list of *ioctl* calls in Linux/i386 kernel 1.3.27. It contains 421 *ioctl*s from `/usr/include/fasm,linuxg/*.h`. For each *ioctl*, you'll find the numerical value, name, and argument type.

An argument type of `const struct foo *` means the argument is input to the kernel. `struct foo *` means the kernel outputs the argument. If the kernel uses the argument for both input and output, this is marked with `// I-O`.

Some *ioctl*s take more arguments or return more values than a single structure. These are marked `// MORE` and are documented further in a separate section.

This list is incomplete. It does not include

- *ioctl*s defined internal to the kernel (`scsi_ioctl.h`).
- *ioctl*s defined in modules distributed separately from the kernel.

And, of course, I may have errors and omissions.

Please e-mail changes and comments to mec@duracef.shout.net. I am particularly interested in loadable modules that define their own *ioctl*s. If you know of such a module, tell me where I can ftp it, and I'll include its *ioctl*s in my next release.

MORE ARGUMENTS

Some `ioctl`s take a pointer to a structure that contains additional pointers. These are documented here in alphabetical order.

`CDROMREADAUDIO` takes an input pointer `const struct cdrom read audio *`. The `buf` field points to an output buffer of length `nframes * CD_FRAMESIZE_RAW`.

`CDROMREADCOOKED`, `CDROMREADMODE1`, `CDROMREADMODE2`, and `CDROM-READDRAW` take an input pointer `const struct cdrom msf *`. They use the same pointer as an output pointer to `char []`. The length varies by request. For `CDROMREADMODE1`, most drivers use `CD_FRAMESIZE`, but the optics storage driver uses `OPT_BLOCKSIZE` instead (both have the numerical value 2048).

<code>CDROMREADCOOKED</code>	<code>char [CD_FRAMESIZE]</code>
<code>CDROMREADMODE1</code>	<code>char [CD_FRAMESIZE or OPT_BLOCKSIZE]</code>
<code>CDROMREADMODE2</code>	<code>char [CD_FRAMESIZE_RAW0]</code>
<code>CDROMREADDRAW</code>	<code>char [CD_FRAMESIZE_RAW]</code>

`EQL_ENSLAVE`, `EQL_EMANCIPATE`, `EQL_GETSLAVECFG`, `EQL_SETSLAVECFG`, `EQL_GETMASTERCFG`, and `EQL_SETMASTERCFG` take a `struct ifreq *`. The `ifr data` field is a pointer to another structure as follows:

<code>EQL_ENSLAVE</code>	<code>const struct slaving_request *</code>
<code>EQL_EMANCIPATE</code>	<code>const struct slaving_request *</code>
<code>EQL_GETSLAVECFG</code>	<code>struct slave_config * // I-O</code>
<code>EQL_SETSLAVECFG</code>	<code>const struct slave_config *</code>
<code>EQL_GETMASTERCFG</code>	<code>struct master_config *</code>
<code>EQL_SETMASTERCFG</code>	<code>const struct master_config *</code>

`FDRAWCMD` takes a `struct floppy raw cmd *`. If `flags & FD_RAW_WRITE` is nonzero, then `data` points to an input buffer of length `length`. If `flags & FD_RAW_READ` is nonzero, then `data` points to an output buffer of length `length`.

`GIO_FONTX` and `PIO_FONTX` take a `struct console font desc *` or a `const struct console_font_desc *`, respectively. `chardata` points to a buffer of `char [charcount]`. This is an output buffer for `GIO_FONTX` and an input buffer for `PIO_FONTX`.

`GIO_UNIMAP` and `PIO_UNIMAP` take a `struct unimapdesc *` or a `const struct unimapdesc *`, respectively. `entries` points to a buffer of `struct unipair [entry ct]`. This is an output buffer for `GIO_UNIMAP` and an input buffer for `PIO_UNIMAP`.

`KDADDIO`, `KDDELIO`, `KDDISABIO`, and `KDENABIO` enable or disable access to I/O ports. They are essentially alternate interfaces to `ioperm`.

`KDMAPDISP` and `KDUNMAPDISP` enable or disable memory mappings or I/O port access. They are not implemented in the kernel.

`SCSI_IOCTL_PROBE_HOST` takes an input pointer `const int *`, which is a length. It uses the same pointer as an output pointer to a `char []` buffer of this length.

`SIOCADDRT` and `SIOCDELRT` take an input pointer whose type depends on the protocol:

Most protocols	<code>const struct rtenry *</code>
<code>AX.25</code>	<code>const struct ax25_route *</code>
<code>NET/ROM</code>	<code>const struct nr_route_struct *</code>

`SIOCGIFCONF` takes a `struct ifconf *`. The `ifc buf` field points to a buffer of length `ifc len` bytes, into which the kernel writes a list of type `struct ifreq []`.

`SIOCSIFHWADDR` takes an input pointer whose type depends on the protocol:

Most protocols	<code>const struct ifreq *</code>
<code>AX.25</code>	<code>const char [AX25_ADDR_LEN]</code>

`TIOCLINUX` takes a `const char *`. It uses this to distinguish several independent subcases. In the following table, `N + foo` means `foo` after an `N`-byte pad. `struct selection` is implicitly defined in `drivers/char/selection.c`:

TIOCLINUX-2	1 + const struct selection *
TIOCLINUX-3	void
TIOCLINUX-4	void
TIOCLINUX-5	4 + const struct f long [8]; g *
TIOCLINUX-6	char *
TIOCLINUX-7	char *
TIOCLINUX-10	1 + const char *

DUPLICATE ioctls

This list does not include `ioctls` in the range `SIOCDEVPRIVATE` and `SIOCPRIVOPRIVATE`:

0x00000001	FDSETPRM	FIBMAP
0x00000002	FDDEFPRM	FIGETBSZ
0x00005382	CDROMAUDIOBUFSIZ	SCSI_IOCTL_GET_IDLUN
0x00005402	SNDCTL_TMR_START	TCSETS
0x00005403	SNDCTL_TMR_STOP	TCSETSW
0x00005404	SNDCTL_TMR_CONTINUE	TCSETSF

Linux, 17 September 1995

ioperm

`ioperm`—Sets port input/output permissions

SYNOPSIS

```
#include <unistd.h>
int ioperm(unsigned long from, unsigned long num, intturn_on);
```

DESCRIPTION

`ioperm` sets the port access permission bits for the process for `num` bytes starting from port address `from` to the value `turn_on`. The use of `ioperm` requires root privileges.

Only the first 0x3ff I/O ports can be specified in this manner. For more ports, the `iopl` function must be used. Permissions are not inherited on `fork`, but on `exec` they are. This is useful for giving port access permissions to nonprivileged tasks.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

CONFORMS TO

`ioperm` is Linux specific.

SEE ALSO

`iopl(2)`

Linux, 21 January 1993

iopl

`iopl`—Changes I/O privilege level

SYNOPSIS

```
#include <unistd.h>
int iopl(int level);
```

DESCRIPTION

`ioPl` changes the I/O privilege level of the current process, as specified in `level`.

This call is necessary to allow 8514-compatible X servers to run under Linux. Because these X servers require access to all 65536 I/O ports, the `ioperm` call is not sufficient.

In addition to granting unrestricted I/O port access, running at a higher I/O privilege level also allows the process to disable interrupts. This will probably crash the system and is not recommended.

The I/O privilege level for a normal process is 0.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

EINVAL	<code>level</code> is greater than 3.
EPERM	The current user is not the superuser.

NOTES FROM THE KERNEL SOURCE

`ioPl` has to be used when you want to access the I/O ports beyond the 0x3ff range: To get the full 65536 ports bitmapped, you'd need 8KB of bitmaps/process, which is a bit excessive.

Linux 0.99.11, 24 July 1993

ipc

`ipc`—System V IPC system calls

SYNOPSIS

```
int ipc(unsigned int call, int first, int second,
int third, void *ptr, long fifth);
```

DESCRIPTION

`ipc` is a common kernel entry point for the System V IPC calls for messages, semaphores, and shared memory. `call` determines which IPC function to invoke; the other arguments are passed through to the appropriate call.

User programs should call the appropriate functions by their usual names. Only standard library implementors and kernel hackers need to know about `ipc`.

Linux 1.2.4, 15 April 1995

kill

`kill`—Sends signal to a process

SYNOPSIS

```
#include <sys/types.h>
#include <signal.h>
int kill(pid_t pid, int sig);
```

DESCRIPTION

The `kill` system call can be used to send any signal to any process group or process.

If `pid` is positive, then signal `sig` is sent to `pid`. In this case, `0` is returned on success and a negative value is returned on error.

If `pid` equals `-1`, then `sig` is sent to every process except the first one, from higher numbers in the `proc` table to lower. In this case, `0` is returned on success, or the error condition resulting from signaling the last process is returned.

If `pid` is less than `-1`, then `sig` is sent to every process in the process group `-pid`. In this case, the number of processes the signal was sent to is returned and a negative value is returned for failure.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

EINVAL	An invalid signal is sent.
ESRCH	The <code>pid</code> or process group does not exist. Note that an existing process might be a zombie, a process that already committed termination, but has not yet been <code>wait()</code> ed for.
EPERM	The effective userID of the process calling <code>kill()</code> is not equal to the effective user ID of <code>pid</code> , unless the superuser called <code>kill()</code> .

BUGS

It is impossible to send a signal to task number one, the `init` process, for which it has not installed a signal handler. This is done to ensure that the system is not brought down accidentally.

CONFORMS TO

SVID, AT&T, POSIX.1, X/OPEN, BSD 4.3

Linux, 1 November 1995

killpg

`killpg`—Sends signal to a process group

SYNOPSIS

```
#include <signal.h>
int killpg(int pgrp, int sig);
```

DESCRIPTION

`killpg` sends the signal `sig` to the process group `pgrp`. See `sigaction(2)` for a list of signals. If `pgrp` is `0`, `killpg` sends the signal to the sending process's process group.

The sending process and members of the process group must have the same effective user ID, or the sender must be the superuser. As a single special case, the continue signal `SIGCONT` may be sent to any process that is a descendant of the current process.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

<code>EINVAL</code>	<code>sig</code> is not a valid signal number.
<code>ESRCH</code>	No process can be found in the process group specified by <code>pgrp</code> .
<code>ESRCH</code>	The process group was given as <code>0</code> , but the sending process does not have a process group.
<code>EPERM</code>	The sending process is not the superuser and one or more of the target processes has an effective user ID different from that of the sending process.

HISTORY

The `killpg` function call appeared in BSD4.0.

SEE ALSO

link

`link`—Makes a new name for a file

SYNOPSIS

```
#include <unistd.h>
int link(const char *oldpath, const char *newpath);
```

DESCRIPTION

`link` creates a new link (also known as a hard link) to an existing file.

If `newpath` exists, it will *not* be overwritten.

This new name may be used exactly as the old one for any operation; both names refer to the same file (and so have the same permissions and ownership) and it is impossible to tell which name was the original.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

<code>EXDEV</code>	<code>oldpath</code> and <code>newpath</code> are not on the same filesystem.
<code>EPERM</code>	The filesystem containing <code>oldpath</code> and <code>newpath</code> does not support the creation of hard links.
<code>EFAULT</code>	<code>oldpath</code> or <code>newpath</code> points outside your accessible address space.
<code>EACCES</code>	Write access to the directory containing <code>newpath</code> is not allowed for the process's effective UID, or one of the directories in <code>oldpath</code> or <code>newpath</code> did not allow search (execute) permission.
<code>ENAMETOOLONG</code>	<code>oldpath</code> or <code>newpath</code> was too long.
<code>ENOENT</code>	A directory component in <code>oldpath</code> or <code>newpath</code> does not exist or is a dangling symbolic link.
<code>ENOTDIR</code>	A component used as a directory in <code>oldpath</code> or <code>newpath</code> is not, in fact, a directory.

ENOMEM	Insufficient kernel memory was available.
EROFS	The file is on a read-only filesystem.
EEXIST	<code>newpath</code> already exists.
EMLINK	The file referred to by <code>oldpath</code> already has the maximum number of links to it.
ELOOP	<code>oldpath</code> or <code>newpath</code> contains a reference to a circular symbolic link, that is, a symbolic link whose expansion contains a reference to itself.
ENOSPC	The device containing the file has no room for the new directory entry.
EPERM	<code>oldpath</code> is the <code>.</code> or <code>..</code> entry of a directory.

NOTES

Hard links, as created by `link`, cannot span filesystems. Use `symlink` if this is required.

CONFORMS TO

SVID, AT&T, POSIX, BSD 4.3

BUGS

On NFS file systems, the return code may be wrong in case the NFS server performs the link creation and dies before it can say so. Use `stat(2)` to find out if the link was created.

`symlink(2)`, `unlink(2)`, `rename(2)`, `open(2)`, `stat(2)`, `ln(1)`, `link(8)`

Linux, 17 August 1994

listen

`listen`—Listens for connections on a socket

SYNOPSIS

```
#include <sys/socket.h>
int listen(int s, int backlog);
```

DESCRIPTION

To accept connections, a socket is first created with `socket(2)`, a willingness to accept incoming connections and a queue limit for incoming connections are specified with `listen`, and then the connections are accepted with `accept(2)`. The `listen` call applies only to sockets of type `SOCK_STREAM` or `SOCK_SEQPACKET`.

The `backlog` parameter defines the maximum length the queue of pending connections may grow to. If a connection request arrives with the queue full, the client might receive an error with an indication of `ECONNREFUSED`, or, if the underlying protocol supports retransmission, the request may be ignored so that retries may succeed.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

EBADF	The argument <code>s</code> is not a valid descriptor.
ENOTSOCK	The argument <code>s</code> is not a socket.
EOPNOTSUPP	The socket is not of a type that supports the operation <code>listen</code> .

HISTORY

The `listen` function call appeared in BSD 4.2.

BUGS

If the socket is of type `af_inet` and the `backlog` argument is greater than 128, it is silently truncated to 128. For portable applications, don't rely on this value since BSD (and at least some BSD-derived systems) limit the backlog to 5.

SEE ALSO

`accept(2)`, `connect(2)`, `socket(2)`

BSD Man Page, 23 July 1993

llseek

`_llseek`—Repositions the read/write file offset

SYNOPSIS

```
#include <unistd.h>
#include <linux/unistd.h>
_syscall5(int, llseek, uint, fd, ulong, hi, ulong, lo, loff_t*,res,uint,wh);
int llseek(unsigned int fd, unsigned long offset_high,
unsigned long offset_low, loff_t * result , unsigned int whence);
```

DESCRIPTION

The `_llseek` function repositions the offset of the file descriptor `fd` to (`offset_high<<32`) | `offset_low` bytes relative to the beginning of the file, the current position in the file, or the end of the file, depending on whether `whence` is `SEEK_SET`, `SEEK_CUR`, or `SEEK_END`, respectively. It returns the resulting file position in the argument `result`.

RETURN VALUES

Upon successful completion, `_llseek` returns 0. Otherwise, a value of -1 is returned and `errno` is set to indicate the error.

ERRORS

<code>EBADF</code>	<code>fd</code> is not an open file descriptor.
<code>EINVAL</code>	<code>whence</code> is invalid.

CONFORMS TO

This function is Linux specific.

BUGS

There is no support for files with a size of 2GB or more.

SEE ALSO

`lseek(2)`

Linux 1.2.9, 10 June 1995

lseek

`lseek`—Repositions read/write file offset

SYNOPSIS

```
#include <unistd.h>
off_t lseek(int fildes, off_t offset, int whence);
```

DESCRIPTION

The `lseek` function repositions the offset of the file descriptor `fil des` to the argument `offset` according to the directive `whence`. The argument `fil des` must be an open file descriptor. `lseek` repositions the file pointer `fil des` as follows:

If `whence` is `SEEK_SET`, the offset is set to `offset` bytes.

If `whence` is `SEEK_CUR`, the offset is set to its current location plus `offset` bytes.

If `whence` is `SEEK_END`, the offset is set to the size of the file plus `offset` bytes.

The `lseek` function allows the file offset to be set beyond the end of the existing end-of-file of the file. If data is later written at this point, subsequent reads of the data in the gap return bytes of zeros (until data is actually written into the gap).

Some devices are incapable of seeking. The value of the pointer associated with such a device is undefined.

RETURN VALUES

Upon successful completion, `lseek` returns the resulting offset location as measured in bytes from the beginning of the file. Otherwise, a value of `-1` is returned and `errno` is set to indicate the error.

ERRORS

<code>EBADF</code>	<code>fil des</code> is not an open file descriptor.
<code>ESPIPE</code>	<code>fil des</code> is associated with a pipe, socket, or FIFO.
<code>EINVAL</code>	<code>whence</code> is not a proper value.

CONFORMS TO

POSIX, BSD 4.3

BUGS

This document's use of `whence` is incorrect English, but maintained for historical reasons.

SEE ALSO

`dup(2)`, `open(2)`, `fseek(3)`

Linux 1.2.9, 10 June 1995

mkdir

`mkdir`—Creates a directory

SYNOPSIS

```
#include <sys/types.h>
#include <fcntl.h>
#include <unistd.h>
int mkdir(const char *pathname, mode_t mode);
```

DESCRIPTION

`mkdir` attempts to create a directory named `pathname`.

`mode` specifies the permissions to use. It is modified by the process's `umask` in the usual way: the permissions of the created file is `(mode & ~umask)`.

The newly created directory will be owned by the effective UID of the process. If the directory containing the file has the set group ID bit set, or if the filesystem is mounted with BSD group semantics, the new directory will inherit the group ownership from its parent; otherwise, it will be owned by the effective GID of the process.

If the parent directory has the set group ID bit set, so will the newly created directory.

RETURN VALUE

`mkdir` returns 0 on success, or -1 if an error occurred (in which case, `errno` is set appropriately).

ERRORS

EEXIST	<code>pathname</code> already exists (not necessarily as a directory).
EFAULT	<code>pathname</code> points outside your accessible address space.
EACCES	The parent directory does not allow write permission to the process, or one of the directories in <code>pathname</code> did not allow search (execute) permission.
ENAMETOOLONG	<code>pathname</code> was too long.
ENOENT	A directory component in <code>pathname</code> does not exist or is a dangling symbolic link.
ENOTDIR	A component used as a directory in <code>pathname</code> is not, in fact, a directory.
ENOMEM	Insufficient kernel memory was available.
EROFS	<code>pathname</code> refers to a file on a read-only filesystem and write access was requested.
ELOOP	<code>pathname</code> contains a reference to a circular symbolic link, that is, a symbolic link whose expansion contains a reference to itself.
ENOSPC	The device containing <code>pathname</code> has no room for the new directory.
ENOSPC	The new directory cannot be created because the user's disk quota is exhausted.

BUGS

In some older versions of Linux (for example, 0.99pl7) all the normal filesystems sometime allow the creation of two files in the same directory with the same name. This occurs only rarely and only on a heavily loaded system. It is believed that this bug was fixed in the Minix filesystem in Linux 0.99pl8 prerelease; and it is hoped that it was fixed in the other filesystems shortly afterward.

There are many infelicities in the protocol underlying NFS.

SEE ALSO

Linux 1.0, 29 March 1994

mknod

`mknod`—Creates a directory

SYNOPSIS

```
#include <sys/types.h>
#include <sys/stat.h>
#include <fcntl.h>
#include <unistd.h>
int mknod(const char *pathname, mode_t mode, dev_t dev);
```

DESCRIPTION

`mknod` attempts to create a filesystem node (file, device special file, or named pipe) named `pathname`, specified by `mode` and `dev`. `mode` specifies both the permissions to use and the type of node to be created.

It should be a combination (using bitwise OR) of one of the file types listed below and the permissions for the new node.

The permissions are modified by the process's `umask` in the usual way: The permissions of the created node is `(mode & ~umask)`.

The file type should be one of `S_IFREG`, `S_IFCHR`, `S_IFBLK`, or `S_IFIFO` to specify a normal file (which will be created empty), character special file, block special file, or FIFO (named pipe), respectively, or 0, which will create a normal file.

If the file type is `S_IFCHR` or `S_IFBLK`, then `dev` specifies the major and minor numbers of the newly created device special file; otherwise, it is ignored.

The newly created node will be owned by the effective UID of the process. If the directory containing the node has the set group ID bit set, or if the filesystem is mounted with BSD group semantics, the new node will inherit the group ownership from its parent directory; otherwise it will be owned by the effective GID of the process.

RETURN VALUE

`mknod` returns 0 on success, or -1 if an error occurred (in which case, `errno` is set appropriately).

ERRORS

<code>EPERM</code>	<code>mode</code> requested creation of something other than a FIFO (named pipe), and the caller is not the superuser; also returned if the filesystem containing <code>pathname</code> does not support the type of node requested.
<code>EINVAL</code>	<code>mode</code> requested creation of something other than a normal file, device special file or FIFO.
<code>EEXIST</code>	<code>pathname</code> already exists.
<code>EFAULT</code>	<code>pathname</code> points outside your accessible address space.
<code>EACCESS</code>	The parent directory does not allow write permission to the process, or one of the directories in <code>pathname</code> did not allow search (execute) permission.
<code>ENAMETOOLONG</code>	<code>pathname</code> was too long.
<code>ENOENT</code>	A directory component in <code>pathname</code> does not exist or is a dangling symbolic link.
<code>ENOTDIR</code>	A component used as a directory in <code>pathname</code> is not, in fact, a directory.
<code>ENOMEM</code>	Insufficient kernel memory was available.
<code>EROFS</code>	<code>pathname</code> refers to a file on a read-only filesystem and write access was requested.
<code>ELOOP</code>	<code>pathname</code> contains a reference to a circular symbolic link, that is, a symbolic link whose expansion contains a reference to itself.
<code>ENOSPC</code>	The device containing <code>pathname</code> has no room for the new node.

BUGS

In some older versions of Linux (for example, 0.99pl7) all the normal filesystems sometime allow the creation of two files in the same directory with the same name. This occurs only rarely and only on a heavily loaded system. It is believed that this bug was fixed in the Minix filesystem in Linux 0.99pl8 prerelease; and it is hoped that it was fixed in the other filesystems shortly afterward.

`mknod` cannot be used to create directories or socket files, and cannot be used to create normal files by users other than the superuser.

There are many infelicities in the protocol underlying NFS.

mlock

`mlock`—Disables paging for some parts of memory

SYNOPSIS

```
#include <sys/mman.h>
int mlock(const void *addr, size_t len);
```

DESCRIPTION

`mlock` disables paging for the memory in the range starting at `addr` with length `len` bytes. All pages that contain a part of the specified memory range are guaranteed to be resident in RAM when the `mlock` system call returns successfully and they are guaranteed to stay in RAM until the pages are unlocked again by `munlock` or `munlockall` or until the process terminates or starts another program with `exec`. Child processes do not inherit page locks across a fork.

Memory locking has two main applications: real-time algorithms and high-security data processing. Real-time applications require deterministic timing, and, like scheduling, paging is one major cause of unexpected program execution delays. Real-time applications will usually also switch to a real-time scheduler with `sched_setscheduler`.

Cryptographic security software often handles critical bytes such as passwords or secret keys as data structures. As a result of paging, these secrets could be transferred onto a persistent swap store medium, where they might be accessible to the enemy long after the security software has erased the secrets in RAM and terminated.

Memory locks do not stack, that is, pages that have been locked several times by calls to `mlock` or `mlockall` will be unlocked by a single call to `munlock` for the corresponding range or by `munlockall`. Pages that are mapped to several locations or by several processes stay locked into RAM as long as they are locked at least at one location or by at least one process.

On POSIX systems on which `mlock` and `munlock` are available, `_POSIX_MEMLOCK_RANGE` is defined in `<unistd.h>` and the value `PAGESIZE` from `<limits.h>` indicates the number of bytes per page.

RETURN VALUE

On success, `mlock` returns 0. On error, `-1` is returned, `errno` is set appropriately, and no changes are made to any locks in the address space of the process.

ERRORS

<code>ENOMEM</code>	Some of the specified address range does not correspond to mapped pages in the address space of the process or the process tried to exceed the maximum number of allowed locked pages.
<code>EPERM</code>	The calling process does not have appropriate privileges. Only root processes are allowed to lock pages.
<code>EINVAL</code>	<code>len</code> was not a positive number.

STANDARDS

POSIX.1b, SVR4

mlockall

`mlockall`—Disables paging for calling process

SYNOPSIS

```
#include <sys/mman.h>
int mlockall(int flags);
```

DESCRIPTION

`mlockall` disables paging for all pages mapped into the address space of the calling process. This includes the pages of the code, data and stack segments, shared libraries, user space kernel data, shared memory, and memory-mapped files. All mapped pages are guaranteed to be resident in RAM when the `mlockall` system call returns successfully and they are guaranteed to stay in RAM until the pages are unlocked again by `munlock` or `munlockall` or until the process terminates or starts another program with `exec`. Child processes do not inherit page locks across a fork.

Memory locking has two main applications: real-time algorithms and high-security data processing. Real-time applications require deterministic timing, and, like scheduling, paging is one major cause of unexpected program execution delays. Real-time applications will usually also switch to a real-time scheduler with `sched_setscheduler`. Cryptographic security software often handles critical bytes such as passwords or secret keys as data structures. As a result of paging, these secrets could be transferred onto a persistent swap store medium, where they might be accessible to the enemy long after the security software has erased the secrets in RAM and terminated. For security applications, only small parts of memory have to be locked, for which `mlock` is available.

The `flags` parameter can be constructed from the logical OR of the following constants:

<code>MCL_CURRENT</code>	Lock all pages that are currently mapped into the address space of the process.
<code>MCL_FUTURE</code>	Lock all pages that will become mapped into the address space of the process in the future. These could be, for instance, new pages required by a growing heap and stack as well as new memory mapped files or shared memory regions.

If `MCL_FUTURE` has been specified and the number of locked pages exceeds the upper limit of allowed locked pages, the system call that caused the new mapping will fail with `ENOMEM`. If these new pages have been mapped by the growing stack, the kernel will deny stack expansion and send a `SIGSEGV`.

Real-time processes should reserve enough locked stack pages before entering the time-critical section, so no page fault can be caused by function calls. This can be achieved by calling a function that has a sufficiently large automatic variable and that writes to the memory occupied by this large array in order to touch these stack pages. This way, enough pages will be mapped for the stack and can be locked into RAM. The dummy writes ensure that not even copy-on-write page faults can occur in the critical section.

Memory locks do not stack, that is, pages that have been locked several times by calls to `mlockall` or `mlock` will be unlocked by a single call to `munlockall`. Pages that are mapped to several locations or by several processes stay locked into RAM as long as they are locked at least at one location or by at least one process.

On POSIX systems on which `mlockall` and `munlockall` are available, `POSIX_MEMLOCK` is defined in `<unistd.h>`.

RETURN VALUE

On success, `mlockall` returns 0. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

<code>ENOMEM</code>	The process tried to exceed the maximum number of allowed locked pages.
<code>EPERM</code>	The calling process does not have appropriate privileges. Only root processes are allowed to lock pages.
<code>EINVAL</code>	Unknown flags were specified.

STANDARDS

POSIX.1b, SVR4

SEE ALSO

mmap, munmap

mmap, munmap—Map or unmap files or devices into memory

SYNOPSIS

```
#include <unistd.h>
#include <sys/mman.h>
#ifdef POSIX MAPPED FILES
void * mmap(void *start, size_t length, int prot, int flags, int fd, off_t offset);
int munmap(void *start, size_t length);
#endif
```

DESCRIPTION

The `mmap` function asks to map `length` bytes starting at `offset` from the file (or other object) specified by `fd` into memory, preferably at address `start`. This latter address is a hint only, and is usually specified as `0`. The actual place where the object is mapped is returned by `mmap`. The `prot` argument describes the desired memory protection. It has the following bits:

<code>PROT_EXEC</code>	Pages may be executed.
<code>PROT_READ</code>	Pages may be read.
<code>PROT_WRITE</code>	Pages may be written.

The `flags` parameter specifies the type of the mapped object, mapping options, and whether modifications made to the mapped copy of the page are private to the process or are to be shared with other references. It has the following bits:

<code>MAP_FIXED</code>	Do not select a different address than the one specified. If the specified address cannot be used, <code>mmap</code> will fail. If <code>MAP_FIXED</code> is specified, <code>start</code> must be a multiple of the pagesize. Use of this option is discouraged.
<code>MAP_SHARED</code>	Share this mapping with all other processes that map this object.
<code>MAP_PRIVATE</code>	Create a private copy-on-write mapping.

These three flags are described in POSIX.4. Linux also knows about `MAP_DENYWRITE`, `MAP_EXECUTABLE`, and `MAP_ANON` (YMOUS).

The `munmap` system call deletes the mappings for the specified address range and causes further references to addresses within the range to generate invalid memory references.

RETURN VALUE

On success, `mmap` returns a pointer to the mapped area. On error, `MAP_FAILED` (`-1`) is returned and `errno` is set appropriately. On success, `munmap` returns `0`, and on failure it returns `-1` and sets `errno` (probably to `EINVAL`).

ERRORS

<code>EBADF</code>	<code>fd</code> is not a valid file descriptor (and <code>MAP_ANONYMOUS</code> was not set).
<code>EACCESS</code>	<code>MAP_PRIVATE</code> was asked, but <code>fd</code> is not open for reading. Or <code>MAP_SHARED</code> was asked and <code>PROT_WRITE</code> is set, <code>fd</code> is not open for writing.
<code>EINVAL</code>	<code>start</code> or <code>length</code> , and <code>offset</code> are too large, or not aligned on a <code>PAGESIZE</code> boundary.
<code>ETXTBUSY</code>	<code>MAP_DENYWRITE</code> was set but the object specified by <code>fd</code> is open for writing.
<code>EAGAIN</code>	The file has been locked, or too much memory has been locked.
<code>ENOMEM</code>	No memory is available.

CONFORMS TO

modify_ldt

modify_ldt—Gets or sets ldt

SYNOPSIS

```
#include <linux/ldt.h> #include <linux/unistd.h>

_syscall3( int, modify_ldt, int, func, void *, ptr, unsigned long, bytecount )

int modify_ldt(int func, void *ptr, unsigned long bytecount);
```

DESCRIPTION

modify_ldt reads or writes the local descriptor table (ldt) for a process. The ldt is a per-process memory-management table used by the i386 processor. For more information on this table, see an Intel 386 processor handbook.

When func is 0, modify_ldt reads the ldt into the memory pointed to by ptr. The number of bytes read is the smaller of bytecount and the actual size of the ldt.

When func is 1, modify_ldt modifies one ldt entry. ptr points to a modify_ldt_ldt_s structure and bytecount must equal the size of this structure.

RETURN VALUE

On success, modify_ldt returns either the actual number of bytes read (for reading) or 0 (for writing). On failure, modify_ldt returns -1 and sets errno.

ERRORS

ENOSYS	func is neither 0 nor 1.
EINVAL	ptr is 0, or func is 1 and bytecount is not equal to the size of the structure modify_ldt_ldt_s, or func is 1 and the new ldt entry has illegal values.
EFAULT	ptr points outside the address space.

get_kernel_syms, create_module, init_module, delete_module

get_kernel_syms, create_module, init_module, delete_module—Loadable module support

SYNOPSIS

```
#include <linux/module.h>

int get_kernel_syms(struct kernel_sym *table);

int create_module(char *module_name, unsigned long size);
```

```

int init_module(char *module_name, char *code, unsigned codesize,
               struct mod_routines *routines, struct symbol_table *symtab);

int delete_module(char *module_name);

struct kernel_sym {
    unsigned long value;
    char name[SYM_MAX_NAME];
};

struct mod_routines {
    int (*init)(void);
    void (*cleanup)(void);
};

struct module_ref {
    struct module *module;
    struct module_ref *next;
};

struct internal_symbol {
    void *addr;
    char *name;
};

struct symbol_table {
    int size; /* total, including string table!!! */
    int n_symbols;
    int n_refs;
    struct internal_symbol symbol[0];
    struct module_ref ref[0];
};

```

DESCRIPTION

These system calls have not yet been included in any library, which means that they have to be called by the `syscall(_NR_function)` mechanism. `get_kernel_syms(table)`; has two uses: First, if `table` is `NULL`, this call will only return the number of symbols, including module names, that are available. This number should be used to reserve memory for that many items of `struct kernel_sym`.

If `table` is not `NULL`, this call will copy all kernel symbols and module names (and version info) from the kernel to the space pointed to by `table`. The entries are ordered in module LIFO order. For each module an entry that describes the module will be followed by entries describing the symbols exported by this module.

Note that for symbols that describe a module, the `value` part of the structure will contain the kernel address of the structure that describes the module.

The `name` part of the structure is the module name prepended with `#`, as in `#my module`. The symbol that describes a module will appear before the symbols defined by this module.

Ahead of the kernel resident symbols, a module name symbol with the “dummy” name `#` will appear. This information can be used to build a table of module references when modules are stacked (or layered). `create_module(module_name, size)`; will allocate `size` bytes of kernel space for a module and also create the necessary kernel structures— called `name`—for the new module. The module will now exist in kernel space, with the status `MOD_UNINITIALIZED`. `init_module(module_name, code, codesize, routines, symtab)`;

This is the actual “module loader” that will load the module named `name` into the kernel. The parameters `code` and `codesize` refer to the relocated binary object module that is `codesize` bytes long. Note that the first 4 bytes will be used as a reference counter in kernel space, updated by the `MOD_INC_USE_COUNT` and `MOD_DEC_USE_COUNT` macros.

The functions described in routines will be used to start and stop the module. These pointers should therefore contain the addresses of the `init_module()` and `cleanup_module()` functions that have to be defined for all loadable modules.

If a module wants to export symbols for use by other modules, or if the module makes references to symbols defined by other modules, the parameter `symtab` has to point to a structure that describes these. A `NULL` value for `symtab` means that no symbols are exported and no references to other modules are made.

The `symtab` that will be copied into the kernel consists of a symbol table structure immediately followed by a string table, containing the names of the symbols defined by the module. The size element has to include the size of this string table as well. Special considerations follow.

The `n_symbols` and `n_refs` elements tells how many symbols and how many module references are included in the symbol table structure. Immediately after these integers, the array of symbol definitions follows. The name element in each `struct` internal symbol should actually not be an ordinary pointer, but instead the offset of the corresponding string table entry relative to the start of the symbol table structure.

When all defined symbols have been listed, the `symbol_table` structure continues with the array of module references, as described by the `struct module_ref` elements. Only the module field of these structures have to be initialized. The module addresses that were obtained from a previous `get_kernel_syms` call, for elements with names starting with `#` should be copied to this field.

If the module could be successfully loaded, and if the call to the module function `init_module()` also succeeds, the status of the module will be changed to `MOD_RUNNING`. Otherwise, the kernel memory occupied by module will be freed.

`delete_module(module_name);` should be used to unload a module. If the module reference count shows that the module is not active, and if there are no references to this module from other modules, the module function `cleanup_module()` will be called. If all these steps succeed, the kernel memory occupied by the module and its structures will be freed.

DIAGNOSTICS

If there are any errors, these functions will return the value `-1`, and the global variable `errno` will contain the error number. A descriptive text will also be written on the console device.

HISTORY

The module support was first conceived by Anonymous.

Linux version by Bas Laarhoven (`bas@vimec.nl`), 0.99.14 version by Jon Tombs (`jon@gtex02.us.es`), extended by Bjorn Ekwall (`bjorn@blox.se`).

BUGS

Naah...

Linux, 25 January 1995

mount, umount

`mount`, `umount`—Mount and unmount filesystems.

SYNOPSIS

```
#include <sys/mount.h>
#include <linux/fs.h>
int mount(const char *specialfile, const char *dir,
const char *filesystemtype, unsigned long rwflag, const void *data);
int umount(const char *specialfile);
int umount(const char *dir);
```

DESCRIPTION

`mount` attaches the filesystem specified by `special file` (which is often a device name) to the directory specified by `dir`.

`umount` removes the attachment of the filesystem specified by `special file` or `dir`.

Only the superuser may mount and unmount filesystems.

The `filesystemtype` argument may take one of the values listed in `/proc/filesystems` (such as `minix`, `ext2`, `msdos`, `proc`, `nfs`, `iso9660`).

The `rwflag` argument has the magic number `0xC0ED` in the top 16 bits, and various mount flags (as defined in `<linux/fs.h>`) in the low order 16 bits:

```
#define MS_RDONLY 1 /* mount read-only */
#define MS_NOSUID 2 /* ignore suid and sgid bits */
#define MS_NODEV 4 /* disallow access to device special files */
#define MS_NOEXEC 8 /* disallow program execution */
#define MS_SYNC 16 /* writes are synced at once */
#define MS_REMOUNT 32 /* alter flags of a mounted FS */
#define MS_MGC_VAL 0xC0ED0000
```

If the magic number is absent, then the last two arguments are not used.

The `data` argument is interpreted by the different filesystems.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

The following error values result from filesystem type independent errors. Each filesystem type may have its own special errors and its own special behavior. See the kernel source code for details.

EPERM	The user is not the superuser.
ENODEV	<code>filesystemtype</code> not configured in the kernel.
ENOTBLK	<code>special file</code> is not a block device (if a device was required).
EBUSY	<code>special file</code> is already mounted. Or it cannot be remounted read-only because it still holds files open for writing. Or, it cannot be mounted on <code>dir</code> because <code>dir</code> is still busy (it is the working directory of some task, the mount point of another device, has open files, and so on).
EINVAL	<code>special file</code> had an invalid superblock. Or, a remount was attempted, while <code>special file</code> was not already mounted on <code>dir</code> . Or, an <code>umount</code> was attempted, while <code>dir</code> was not a mount point.
EFAULT	One of the pointer arguments points outside the user address space.
ENOMEM	The kernel could not allocate a free page to copy filenames or data into.
ENAMETOOLONG	A pathname was longer than <code>MAXPATHLEN</code> .
ENOENT	A pathname was empty or had a nonexistent component.
ENOTDIR	The second argument, or a prefix of the first argument, is not a directory.
EACCES	A component of a path was not searchable. Or, mounting a read-only filesystem was attempted without giving the <code>MS_RDONLY</code> flag. Or, the block device <code>special file</code> is located on a filesystem mounted with the <code>MS_NODEV</code> option.
ENXIO	The major number of the block device <code>special file</code> is out of range.
EMFILE	(In case no block device is required:) Table of dummy devices is full.

CONFORMS TO

These functions are rather Linux specific.

mprotect

mprotect—Controls allowable accesses to a region of memory

SYNOPSIS

```
#include <sys/mman.h>
int mprotect(caddr_t addr, size_t *len, int prot);
```

DESCRIPTION

mprotect controls how a section of memory can be accessed. If an access is disallowed by the protection given it, the program receives a SIGSEGV.

prot is a bitwise-OR of the following values:

PROT_NONE	The memory cannot be accessed at all.
PROT_READ	The memory can be read.
PROT_WRITE	The memory can be written to.
PROT_EXEC	The memory can contain executing code.

The new protection replaces any existing protection. For example, if the memory had previously been marked PROT_READ, and mprotect is then called with prot PROT_WRITE, it will no longer be readable.

RETURN VALUE

On success, mprotect returns 0. On error, -1 is returned and errno is set appropriately.

ERRORS

EINVAL	addr is not a valid pointer.
EFAULT	The memory cannot be accessed.
EACCES	The memory cannot be given the specified access. This can happen, for example, if you mmap(2) a file to which you have read-only access, then ask mprotect to mark it PROT_WRITE.
ENOMEM	Internal kernel structures could not be allocated.

EXAMPLE

```
#include <stdio.h>
#include <stdlib.h>
#include <errno.h>
#include <sys/mman.h>

int
main(void)
{
    char *p;
    char c;
```

```

/* Allocate a buffer; it will have the default
   protection of PROT_READ|PROT_WRITE. */
p = malloc(1024);
if (!p) {
    perror("Couldn't malloc(1024)");
    exit(errno);
}

c = p[666];          /* Read; ok */
p[666] = 42;        /* Write; ok */

/* Mark the buffer read-only. */
if (mprotect(p, 1024, PROT_READ)) {
    perror("Couldn't mprotect");
    exit(errno);
}

c = p[666];          /* Read; ok */
p[666] = 42;        /* Write; program dies on SIGSEGV */

exit(0);
}

```

mremap

mremap—Remaps a virtual memory address

SYNOPSIS

```

#include <unistd.h>
#include <sys/mman.h>
void * mremap(void * old_address, size_t old_size , size_t new_size, unsigned long flags)

```

DESCRIPTION

mremap expands (or shrinks) an existing memory mapping, potentially moving it at the same time (controlled by the flags argument and the available virtual address space).

old_address is the old address of the virtual memory block that you want to expand (or shrink). Note that old_address has to be page aligned. old_size is the old size of the virtual memory block. new_size is the requested size of the virtual memory block after the resize.

The flags argument is a bitmap of flags.

In Linux the memory is divided into pages. A user process has one or linear virtual memory segments. Each virtual memory segment has one or more mappings to real memory pages (in the page table). Each virtual memory segment has its own protection (access rights), which may cause a segmentation violation if the memory is accessed incorrectly (for example, writing to a read-only segment). Accessing virtual memory outside of the segments will also cause a segmentation violation.

mremap uses the Linux page table scheme. mremap changes the mapping between virtual addresses and memory pages. This can be used to implement a very efficient realloc.

FLAGS

`MREMAP_MAYMOVE` Indicates whether the operation should fail, or changes the virtual address if the resize cannot be done at the current virtual address.

RETURN VALUE

On success, `mremap` returns a pointer to the new virtual memory area. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

`EINVAL` An invalid argument was given. Most likely `old_address` was not page aligned.

`EFAULT` Segmentation fault. Some address in the range `old_address` to `old_address+old_size` is an invalid virtual memory address for this process. You can also get `EFAULT` even if there exist mappings that cover the whole address space requested, but those mappings are of different types.

`EAGAIN` The memory segment is locked and cannot be remapped.

`ENOMEM` The memory area cannot be expanded at the current virtual address, and the `MREMAP_MAYMOVE` flag is not set in `flags`. Or there is not enough (virtual) memory available.

Linux 1.3.87, 12 April 1996

msgctl

`msgctl`—Handles message control operations

SYNOPSIS

```
# include <sys/types.h>
# include <sys/ipc.h>
# include <sys/msg.h>
int msgctl ( int msqid, int cmd, struct msqid_ds *buf );
int cmd, struct msqid_ds *buf;
```

DESCRIPTION

The function performs the control operation specified by `cmd` on the message queue with identifier `msqid`. Legal values for `cmd` are

`IPC_STAT` Copies info from the message queue data structure into the structure pointed to by `buf`. The user must have read access privileges on the message queue.

`IPC_SET` Writes the values of some members of the `msqid_ds` structure pointed to by `buf` to the message queue data structure, updating also its `msg_ctime` member. Considered members from the user-supplied `struct msqid_ds` pointed to by `buf` are `msg_perm.uid`, `msg_perm.gid`, and `msg_perm.mode` /* only lowest 9-bits */ `msg_qbytes`.

The calling process effective user ID must be one among superuser, creator or owner of the message queue. Only the superuser can raise the `msg_qbytes` value beyond the system parameter `MSGMNB`.

`IPC_RMID` Remove immediately the message queue and its data structures awakening all waiting reader and writer processes (with an error return and `errno` set to `EIDRM`). The calling process effective user ID must be one among superuser, creator or owner of the message queue.

RETURN VALUE

If successful, the return value will be 0; otherwise, the return value will be -1 with `errno` indicating the error.

ERRORS

For a failing return, `errno` will be set to one of the following values:

EACCESS	The argument <code>cmd</code> is equal to <code>IPC_STAT</code> , but the calling process has no read access permissions on the message queue <code>msqid</code> .
EFAULT	The argument <code>cmd</code> has value <code>IPC_SET</code> or <code>IPC_STAT</code> , but the address pointed to by <code>buf</code> isn't accessible.
EIDRM	The message queue was removed.
EINVAL	Invalid value for <code>cmd</code> or <code>msqid</code> .
EPERM	The argument <code>cmd</code> has value <code>IPC_SET</code> or <code>IPC_RMID</code> , but the calling process effective user ID has insufficient privileges to execute the command. Note that this is also the case of a nonsuperuser process trying to increase the <code>msg_bytes</code> value beyond the value specified by the system parameter <code>MSGMNB</code> .

NOTES

The `IPC_INFO`, `MSG_STAT`, and `MSG_INFO` control calls are used by the `ipcs(1)` program to provide information on allocated resources. In the future these can be modified as needed or moved to a `proc` file system interface.

SEE ALSO

`ipc(5)`, `msgget(2)`, `msgsnd(2)`, `msgrcv(2)`

Linux 0.99.13, 1 November 1993

msgget

`msgget`—Gets a message queue identifier

SYNOPSIS

```
# include <sys/types.h>
# include <sys/ipc.h>
# include <sys/msg.h>
int msgget ( key_t key, int msgflg );
```

DESCRIPTION

The function returns the message queue identifier associated to the value of the `key` argument. A new message queue is created if `key` has value `IPC_PRIVATE` or `key` isn't `IPC_PRIVATE`, no existing message queue is associated to `key`, and `IPC_CREAT` is asserted in `msgflg` (that is, `msgflg & IPC_CREAT` isn't 0). The presence in `msgflg` of the fields `IPC_CREAT` and `IPC_EXCL` plays the same role, with respect to the existence of the message queue, as the presence of `O_CREAT` and `O_EXCL` in the mode argument of the `open(2)` system call: That is, the `msgget` function fails if `msgflg` asserts both `IPC_CREAT` and `IPC_EXCL` and a message queue already exists for `key`.

Upon creation, the lower 9 bits of the argument `msgflg` define the access permissions (for owner, group, and others) to the message queue in the same format, and with the same meaning, as for the access permissions parameter in the `open(2)` or `creat(2)` system calls (though the execute permissions are not used by the system).

Furthermore, while creating, the system call initializes the system message queue data structure `msqid_ds` as follows:

```
msg_perm.cuid and msg_perm.uid are set to the effective user ID of the calling process.
msg_perm.cgid and msg_perm.gid are set to the effective group ID of the calling process.
```

The lowest-order 9 bits of `msg_perm.mode` are set to the lowest-order 9 bit of `msgflg`.

`msg_qnum`, `msg_lspid`, `msg_lrpid`, `msg_stime`, and `msg_rtime` are set to 0.

`msg_ctime` is set to the current time.

`msg_qbytes` is set to the system limit `MSGMNB`.

If the message queue already exists, the access permissions are verified, and a check is made to see whether it is marked for destruction.

RETURN VALUE

If successful, the return value will be the message queue identifier (a positive integer), otherwise -1 with `errno` indicating the error.

ERRORS

For a failing return, `errno` will be set to one of the following values:

EACCES	A message queue exists for <code>key</code> , but the calling process has no access permissions to the queue.
EEXIST	A message queue exists for <code>key</code> and <code>msgflg</code> was asserting both <code>IPC_CREAT</code> and <code>IPC_EXCL</code> .
EIDRM	The message queue is marked as to be removed.
ENOENT	No message queue exists for <code>key</code> and <code>msgflg</code> wasn't asserting <code>IPC_CREAT</code> .
ENOMEM	A message queue has to be created but the system has not enough memory for the new data structure.
ENOSPC	A message queue has to be created but the system limit for the maximum number of message queues (<code>MSGMNI</code>) would be exceeded.

NOTES

`IPC_PRIVATE` isn't a flag field, but a `key_t` type. If this special value is used for `key`, the system call ignores everything but the lowest-order 9 bits of `msgflg` and creates a new message queue (on success).

The following is a system limit on message queue resources affecting a `msgget` call:

MSGMNI	Systemwide maximum number of message queues; policy dependent.
--------	--

BUGS

Use of `IPC_PRIVATE` doesn't inhibit other processes the access to the allocated message queue.

As for the files, there is currently no intrinsic way for a process to ensure exclusive access to a message queue. Asserting both `IPC_CREAT` and `IPC_EXCL` in `msgflg` only ensures (on success) that a new message queue will be created; it doesn't imply exclusive access to the message queue.

Linux 0.99.13, 1 November 1993

msgop

`msgop`—Completes message operations

SYNOPSIS

```
# include <sys/types.h>
# include <sys/ipc.h>
# include <sys/msg.h>
```

```
int msgsnd ( int msqid, struct msgbuf *msgp, int msgsz, int msgflg );
int msgrcv ( int msqid, struct msgbuf *msgp, int msgsz, long msgtyp, int msgflg );
```

DESCRIPTION

To send or receive a message, the calling process allocates a structure that looks like the following:

```
struct msgbuf {
    long mtype; /* message type, must be > 0 */
    char mtext[1]; /* message data */
};
```

but with an array `mtext` of size `msgsz`, a nonnegative integer value. The structure member `mtype` must have a strictly positive integer value that can be used by the receiving process for message selection (see the section about `msgrcv`).

The calling process must have write access permissions to send and read access permissions to receive a message on the queue.

The `msgsnd` system call queues a copy of the message pointed to by the `msgp` argument on the message queue whose identifier is specified by the value of the `msqid` argument.

The argument `msgflg` specifies the system call behavior if queuing the new message will require more than `msg_qbytes` in the queue. Asserting `IPC_NOWAIT`, the message will not be sent and the system call fails, returning with `errno` set to `EAGAIN`. Otherwise the process is suspended until the condition for the suspension no longer exists (in which case the message is sent and the system call succeeds), or the queue is removed (in which case the system call fails with `errno` set to `EIDRM`), or the process receives a signal that has to be caught (in which case the system call fails with `errno` set to `EINTR`).

Upon successful completion, the message queue data structure is updated as follows:

<code>msg_lspid</code>	Set to the process ID of the calling process.
<code>msg_qnum</code>	Incremented by 1.
<code>msg_stime</code>	Set to the current time.

The system call `msgrcv` reads a message from the message queue specified by `msqid` into the `msgbuf` pointed to by the `msgp` argument, removing from the queue, on success, the read message.

The argument `msgsz` specifies the maximum size in bytes for the member `mtext` of the structure pointed to by the `msgp` argument. If the message text has length greater than `msgsz`, then if the `msgflg` argument asserts `MSG_NOERROR`, the message text will be truncated (and the truncated part will be lost); otherwise, the message isn't removed from the queue and the system call fails, returning with `errno` set to `E2BIG`.

The argument `msgtyp` specifies the type of message requested as follows:

If `msgtyp` is 0, the message on the queue's front is read.

If `msgtyp` is greater than 0, the first message on the queue of type `msgtyp` is read if `MSG_EXCEPT` isn't asserted by the `msgflg` argument; otherwise, the first message on the queue of type not equal to `msgtyp` will be read.

If `msgtyp` is less than 0, the first message on the queue with the lowest type less than or equal to the absolute value of `msgtyp` will be read.

The `msgflg` argument asserts none, one, or more (OR-ing them) among the following flags:

<code>IPC_NOWAIT</code>	For immediate return if no message of the requested type is on the queue. The system call fails with <code>errno</code> set to <code>ENOMSG</code> .
<code>MSG_EXCEPT</code>	Used with <code>msgtyp</code> greater than 0 to read the first message on the queue with message type that differs from <code>msgtyp</code> .
<code>MSG_NOERROR</code>	To truncate the message text if longer than <code>msgsz</code> bytes.

If no message of the requested type is available and `IPC_NOWAIT` isn't asserted in `msgflg`, the calling process is blocked until one of the following conditions occurs:

A message of the desired type is placed on the queue.

The message queue is removed from the system. In such a case the system call fails with `errno` set to `EIDRM`.

The calling process receives a signal that has to be caught. In such a case the system call fails with `errno` set to `EINTR`.

Upon successful completion, the message queue data structure is updated as follows:

<code>msg_lrpid</code>	Set to the process ID of the calling process.
<code>msg_qnum</code>	Decremented by 1.
<code>msg_rtime</code>	Set to the current time.

RETURN VALUE

On a failure, both functions return `-1` with `errno` indicating the error; otherwise, `msgsnd` returns `0` and `msgrvc` returns the number of bytes actually copied into the `mtext` array.

ERRORS

When `msgsnd` fails, at return `errno` will be set to one of the following values:

<code>EAGAIN</code>	The message can't be sent due to the <code>msg_qbytes</code> limit for the queue, and <code>IPC_NOWAIT</code> was asserted in <code>msgflg</code> .
<code>EACCES</code>	The calling process has no write access permissions on the message queue.
<code>EFAULT</code>	The address pointed to by <code>msgp</code> isn't accessible.
<code>EIDRM</code>	The message queue was removed.
<code>EINTR</code>	Sleeping on a full message queue condition, the process received a signal that had to be caught.
<code>EINVAL</code>	Invalid <code>msgqid</code> value, or nonpositive <code>mtype</code> value, or invalid <code>msgsz</code> value (less than <code>0</code> or greater than the system value <code>MSGMAX</code>).
<code>ENOMEM</code>	The system has not enough memory to make a copy of the supplied <code>msgbuf</code> .

When `msgrvc` fails, at return `errno` will be set to one of the following values:

<code>E2BIG</code>	The message text length is greater than <code>msgsz</code> and <code>MSG_NOERROR</code> isn't asserted in <code>msgflg</code> .
<code>EACCES</code>	The calling process has no read access permissions on the message queue.
<code>EFAULT</code>	The address pointed to by <code>msgp</code> isn't accessible.
<code>EIDRM</code>	While the process was sleeping to receive a message, the message queue was removed.
<code>EINTR</code>	While the process was sleeping to receive a message, the process received a signal that had to be caught.
<code>EINVAL</code>	Illegal <code>msgqid</code> value, or <code>msgsz</code> less than <code>0</code> .
<code>ENOMSG</code>	<code>IPC_NOWAIT</code> was asserted in <code>msgflg</code> and no message of the requested type existed on the message queue.

NOTES

The followings are system limits affecting a `msgsnd` system call:

<code>MSGMAX</code>	Maximum size for a message text; the implementation set this value to 4080 bytes.
<code>MSGMNB</code>	Default maximum size in bytes of a message queue: policy dependent. The superuser can increase the size of a message queue beyond <code>MSGMNB</code> by a <code>msgctl</code> system call.

The implementation has no intrinsic limits for the systemwide maximum number of message headers (`MSGTQL`) and for the systemwide maximum size in bytes of the message pool (`MSGPOOL`).

Linux 0.99.13, 1 November 1993

msync

`msync`—Synchronizes a file with a memory map

SYNOPSIS

```
#include <unistd.h>
#include <sys/mman.h>

#ifdef POSIX_MAPPED_FILES
#ifdef POSIX_SYNCHRONIZED_IO

int msync(const void *start, size_t length, int flags);
#endif
#endif
```

DESCRIPTION

`msync` flushes changes made to the in-core copy of a file that was mapped into memory using `mmap(2)` back to disk. Without use of this call, there is no guarantee that changes are written back before `munmap(2)` is called. To be more precise, the part of the file that corresponds to the memory area starting at `start` and having length `length` is updated. The `flags` argument may have the bits `MS_ASYNC`, `MS_SYNC`, and `MS_INVALIDATE` set, but not both `MS_ASYNC` and `MS_SYNC`. `MS_ASYNC` specifies that an update be scheduled, but the call returns immediately. `MS_SYNC` asks for an update and waits for it to complete. `MS_INVALIDATE` asks to invalidate other mappings of the same file (so that they can be updated with the fresh values just written).

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

EINVAL	<code>start</code> is not a multiple of <code>PAGESIZE</code> , or any bit other than <code>MS_ASYNC</code> <code>MS_INVALIDATE</code> <code>MS_SYNC</code> is set in <code>flags</code> .
EFAULT	The indicated memory (or part of it) was not mapped.

CONFORMS TO

POSIX.4.

munlock

`munlock`—Reenables paging for some parts of memory

SYNOPSIS

```
#include <sys/mman.h>
int munlock(const void *addr, size_t len);
```

DESCRIPTION

`munlock` reenables paging for the memory in the range starting at `addr` with length `len` bytes. All pages that contain a part of the specified memory range can after calling `munlock` be moved to external swap space again by the kernel.

Memory locks do not stack, that is, pages that have been locked several times by calls to `mlock` or `mlockall` will be unlocked by a single call to `munlock` for the corresponding range or by `munlockall`. Pages that are mapped to several locations or by several processes stay locked into RAM as long as they are locked at least at one location or by at least one process.

On POSIX systems on which `mlock` and `munlock` are available, `_POSIX_MEMLOCK_RANGE` is defined in `<unistd.h>` and the value `PAGESIZE` from `<limits.h>` indicates the number of bytes per page.

RETURN VALUE

On success, `munlock` returns 0. On error, -1 is returned, `errno` is set appropriately, and no changes are made to any locks in the address space of the process.

ERRORS

<code>ENOMEM</code>	Some of the specified address range does not correspond to mapped pages in the address space of the process.
<code>EINVAL</code>	<code>len</code> was not a positive number.

STANDARDS

POSIX.1b, SVR4

SEE ALSO

`mlock(2)`, `mlockall(2)`, `munlockall(2)`.

munlockall

`munlockall`—Reenables paging for calling process

SYNOPSIS

```
#include <sys/mman.h>
int munlockall(void);
```

DESCRIPTION

`munlockall` reenables paging for all pages mapped into the address space of the calling process.

Memory locks do not stack, that is, pages that have been locked several times by calls to `mlock` or `mlockall` will be unlocked by a single call to `munlockall`. Pages that are mapped to several locations or by several processes stay locked into RAM as long as they are locked at least at one location or by at least one process.

On POSIX systems on which `mlockall` and `munlockall` are available, `_POSIX_MEMLOCK` is defined in `<unistd.h>`.

RETURN VALUE

On success, `munlockall` returns 0. On error, -1 is returned and `errno` is set appropriately.

STANDARDS

POSIX.1b, SVR4

SEE ALSO

mlockall(2), mlock(2), munlock(2)

Linux 1.3.43, 26 November 1995

nanosleep

nanosleep—Pauses execution for a specified time

SYNOPSIS

```
#include <time.h>

int nanosleep(const struct timespec *req, struct timespec *rem);
```

DESCRIPTION

nanosleep delays the execution of the program for at least the time specified in **req*. The function can return earlier if a signal has been delivered to the process. In this case, it returns -1, sets *errno* to *EINTR*, and writes the remaining time into the structure pointed to by *rem* unless *rem* is NULL. The value of **rem* can then be used to call nanosleep again and complete the specified pause.

The structure *timespec* is used to specify intervals of time with nanosecond precision. It is specified in *<time.h>* and has the form

```
struct timespec
{
    time_t tv_sec; /* seconds */
    long tv_nsec; /* nanoseconds */
};
```

The value of the nanoseconds field must be in the range 0 to 999 999 999.

Compared to *sleep(3)* and *usleep(3)*, nanosleep has the advantage of not affecting any signals; it is standardized by POSIX, it provides higher timing resolution, and it allows to continue a sleep that has been interrupted by a signal more easily.

ERRORS

In case of an error or exception, the nanosleep system call returns -1 instead of 0 and sets *errno* to one of the following values:

EINTR	The pause has been interrupted by a nonblocked signal that was delivered to the process. The remaining sleep time has been written into <i>*rem</i> so that the process can easily call nanosleep again and continue with the pause.
EINVAL	The value in the <i>tv_nsec</i> field was not in the range 0 to 999 999 999 or <i>tv_sec</i> was negative.

BUGS

The current implementation of nanosleep is based on the normal kernel timer mechanism, which has a resolution of *1/HZ*s (that is, 10ms on Linux/i386 and 1ms on Linux/Alpha). Therefore, nanosleep pauses always for at least the specified time; however, it can take up to 10ms longer than specified until the process becomes runnable again. For the same reason, the value returned in case of a delivered signal in **rem* is usually rounded to the next larger multiple of *1/HZ*s.

Because some applications require much more precise pauses (for example, in order to control some time-critical hardware), nanosleep is also capable of short high-precision pauses. If the process is scheduled under a real-time policy such as *SCHED_FIFO* or *SCHED_RR*, then pauses of up to 2ms will be performed as busy waits with microsecond precision.

STANDARDS

POSIX.1b

Linux 1.3.85, 10 April 1996

nice

`nice`—Changes process priority

SYNOPSIS

```
#include <unistd.h>
int nice(int inc);
```

DESCRIPTION

`nice` adds `inc` to the priority for the calling PID. Note that only the superuser may specify a negative increment, or priority increase. Note that internally, a higher number is a higher priority. Do not confuse this with the priority scheme as used by the `nice` interface.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

`EPERM` A nonsuperuser attempts to do a priority increase, a numerical decrease, by supplying a negative `inc`.

CONFORMS TO

SVID EXT, AT&T, X/OPEN, BSD 4.3

oldfstat, oldlstat, oldstat, oldolduname, olduname

`oldfstat`, `oldlstat`, `oldstat`, `oldolduname`, `olduname`—Obsolete system calls

SYNOPSIS

Obsolete system calls.

DESCRIPTION

The Linux 1.3.6 kernel implements these calls to support old executables. These calls return structures that have grown since their first implementations, but old executables must continue to receive old smaller structures.

Current executables should be linked with current libraries and never use these calls.

SEE ALSO

Linux 1.3.6, 22 July 1995

open, creat

open, creat—Open and possibly create a file or device

SYNOPSIS

```
#include <sys/types.h>
#include <sys/stat.h>
#include <fcntl.h>
int open(const char *pathname,int flags);
int open(const char *pathname,int flags,mode_t mode);
int creat(const char *pathname,mode_t mode);
```

DESCRIPTION

`open` attempts to open a file and return a file descriptor (a small, nonnegative integer for use in read, write, and so on).

`flags` is one of `O_RDONLY`, `O_WRONLY`, or `O_RDWR`, which request opening the file read-only, write-only, or read/write, respectively.

`flags` may also be bitwise-ORed with one or more of the following:

<code>O_CREAT</code>	If the file does not exist it will be created.
<code>O_EXCL</code>	When used with <code>O_CREAT</code> , if the file already exists, it is an error and the open will fail. <i>See the “Bugs” section, though.</i>
<code>O_NOCTTY</code>	If <code>pathname</code> refers to a terminal device—see <code>tty(4)</code> —it will not become the process’s controlling terminal even if the process does not have one.
<code>O_TRUNC</code>	If the file already exists, it will be truncated.
<code>O_APPEND</code>	The file is opened in append mode. Initially, and before each write, the file pointer is positioned at the end of the file, as if with <code>lseek</code> .
<code>O_NONBLOCK</code> or <code>O_NDELAY</code>	The file is opened in nonblocking mode. Neither the <code>open</code> nor any subsequent operations on the file descriptor that is returned will cause the calling process to wait.
<code>O_SYNC</code>	The file is opened for synchronous I/O. Any writes on the resulting file descriptor will block the calling process until the data has been physically written to the underlying hardware. <i>See the “Bugs” section, though.</i>

Some of these optional flags can be altered using `fcntl` after the file has been opened.

`mode` specifies the permissions to use if a new file is created. It is modified by the process’s `umask` in the usual way: The permission of the created file is $(mode \& \sim umask)$.

The following symbolic constants are provided for `mode`:

<code>S_IRWXU</code>	00700 user (file owner) has read, write, and execute permission.
<code>S_IRUSR</code> (<code>S_IREAD</code>)	00400 user has read permission.
<code>S_IWUSR</code> (<code>S_IWRITE</code>)	00200 user has write permission.
<code>S_IXUSR</code> (<code>S_IEXEC</code>)	00100 user has execute permission.
<code>S_IRWXG</code>	00070 group has read, write, and execute permission.
<code>S_IRGRP</code>	00040 group has read permission.
<code>S_IWGRP</code>	00020 group has write permission.
<code>S_IXGRP</code>	00010 group has execute permission.
<code>S_IRWXO</code>	00007 others have read, write, and execute permission.
<code>S_IROTH</code>	00004 others have read permission.
<code>S_IWOTH</code>	00002 others have write permission.
<code>S_IXOTH</code>	00001 others have execute permission.

`mode` should always be specified when `O_CREAT` is in the `flags`, and is ignored otherwise.

`creat` is equivalent to `open` with `flags` equal to `O_CREAT|O_WRONLY|O_TRUNC`.

RETURN VALUE

`open` and `creat` return the new file descriptor, or `-1` if an error occurred (in which case `errno` is set appropriately). Note that `open` can open device-special files, but `creat` cannot create them—use `mknod(2)` instead.

ERRORS

EEXIST	<code>pathname</code> already exists and <code>O_CREAT</code> and <code>O_EXCL</code> were used.
EISDIR	<code>pathname</code> refers to a directory and the access requested involved writing.
ETXTBSY	<code>pathname</code> refers to an executable image which is currently being executed and write access was requested.
EFAULT	<code>pathname</code> points outside your accessible address space.
EACCESS	The requested access to the file is not allowed, or one of the directories in <code>pathname</code> did not allow search (execute) permission.
ENAMETOOLONG	<code>pathname</code> was too long.
ENOENT	A directory component in <code>pathname</code> does not exist or is a dangling symbolic link.
ENOTDIR	A component used as a directory in <code>pathname</code> is not, in fact, a directory.
EMFILE	The process already has the maximum number of files open.
ENFILE	The limit on the total number of files open on the system has been reached.
ENOMEM	Insufficient kernel memory was available.
EROFS	<code>pathname</code> refers to a file on a read-only filesystem and write access was requested.
ELOOP	<code>pathname</code> contains a reference to a circular symbolic link, that is, a symbolic link whose expansion contains a reference to itself.
ENOSPC	<code>pathname</code> was to be created but the device containing <code>pathname</code> has no room for the new file.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

BUGS

`O_SYNC` is not currently implemented (as of Linux 0.99pl7).

There are many infelicities in the protocol underlying NFS, affecting amongst others `O_SYNC`, `O_NDELAY`, and `O_APPEND`.

`O_EXCL` is broken on NFS filesystems; programs that rely on it for performing locking tasks will contain a race condition. The solution for performing atomic file locking using a lockfile is to create a unique file on the same `fs` (for example, incorporating hostname and PID), use `link(2)` to make a link to the lockfile, and use `stat(2)` on the unique file to check if its link count has increased to 2. Do not use the return value of the `link()` call.

Linux 0.99.7, 21 July 1993

outb, outw, outl, outsb, outsw, outsl

`outb`, `outw`, `outl`, `outsb`, `outsw`, `outsl`—Port output

`inb`, `inw`, `inl`, `insb`, `insw`, `insl`—Port input

`outb_p`, `outw_p`, `outl_p`, `inb_p`, `inw_p`, `inl_p`—Pause I/O

DESCRIPTION

This family of functions is used to do low-level port input and output. They are primarily designed for internal kernel use, but can be used from user space, given the following information in addition to that given in `outb(9)`.

You compile with `-O` or `-O2` or something similar. The functions are defined as inline macros and will not be substituted in without optimization enabled, causing unresolved references at link time.

You use `ioperm(2)` or alternatively `iopl(2)` to tell the kernel to allow the user space application to access the I/O ports in question. Failure to do this will cause the application to receive a segmentation fault.

CONFORMS TO

`outb` and friends are hardware specific. The `port` and `value` arguments are in the opposite order from most DOS implementations.

SEE ALSO

`outb(9)`, `ioperm(2)`, `iopl(2)`

pause

`pause`—Waits for signal

SYNOPSIS

```
#include <unistd.h>
int pause(void);
```

DESCRIPTION

The `pause` system call causes the invoking process to sleep until a signal is received.

RETURN VALUE

`pause` always returns `-1`, and `errno` is set to `ERESTARTNOHAND`.

ERRORS

`EINTR` Signal was received.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

`kill(2)`, `select(2)`, `signal(2)`

Linux, 31 August 1995

personality

`personality`—Sets the process execution domain

SYNOPSIS

```
int personality(unsigned long persona);
```

DESCRIPTION

Linux supports different execution domains, or personalities, for each process. Among other things, execution domains tell Linux how to map signal numbers into signal actions. The execution domain system allows Linux to provide limited support for binaries compiled under other UNIX-like operating systems.

`personality` will make the execution domain referenced by `persona` the new execution domain of the current process.

RETURN VALUE

On success, `persona` is made the new execution domain and the previous `persona` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

`EINVAL` `persona` does not refer to a valid execution domain.

FILE

`/usr/include/linux/personality.h`

CONFORMS TO

`personality` is Linux specific.

Linux 2.0, 22 July 1996

phys

`phys`—Allows a process to access physical addresses (this command is not implemented)

SYNOPSIS

```
int phys(int physnum, char *virtaddr, longsize, char *physaddr);
```

DESCRIPTION

Warning: Because this function is not implemented as of Linux 0.99.11, it will always return `-1` and set `errno` to `ENOSYS`.

`phys` maps arbitrary physical memory into a process's virtual address space. `physnum` is a number (0–3) that specifies which of the four physical spaces to set up. Up to four `phys` calls can be active at any one time. `virtaddr` is the process's virtual address. `size` is the number of bytes to map in. `physaddr` is the physical address to map in.

Valid `virtaddr` and `physaddr` values are constrained by hardware and must be at an address multiple of the resolution of the CPU's memory management scheme. If `size` is nonzero, `size` is rounded up to the next MMU resolution boundary. If `size` is 0, any previous `phys(2)` mapping for that `physnum` is nullified.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

CONFORMS TO

version 7 AT&T UNIX

BUGS

`phys` is very machine dependent.

SEE ALSO

`mmap(2)`, `munmap(2)`

Linux 0.99.11, 24 July 1993

pipe

`pipe`—Creates a pipe

SYNOPSIS

```
#include <unistd.h>
int pipe(int filedes[2]);
```

DESCRIPTION

`pipe` creates a pair of file descriptors, pointing to a pipe inode, and places them in the array pointed to by `filedes`. `filedes[0]` is for reading, `filedes[1]` is for writing.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned and `errno` is set appropriately.

ERRORS

EMFILE	Too many file descriptors are in use by the process.
ENFILE	The system file table is full.
EFAULT	<code>filedes</code> is not valid.

SEE ALSO

`read(2)`, `write(2)`, `fork(2)`, `socketpair(2)`

Linux 0.99.11, 23 July 1993

profil

`profil`—Execution time profile

SYNOPSIS

```
#include <unistd.h>
int profil(char *buf, int bufsiz, int offset, int scale);
```

DESCRIPTION

Under Linux 0.99.11, `profil` is not implemented in the kernel. Instead, the DLL 4.4.1 libraries provide a user-space implementation.

`buf` points to `bufsiz` bytes of core. Every virtual 10 milliseconds, the user's program counter (PC) is examined: `offset` is subtracted and the result is multiplied by `scale`. If this address is in `buf`, the word pointed to is incremented.

If `scale` is less than 2 or `bufsiz` is 0, profiling is disabled.

RETURN VALUE

`0` is always returned.

BUGS

`profil` cannot be used on a program that also uses `ITIMER_PROF` itimers.

Calling `profil` with an invalid `buf` will result in a core dump.

True kernel profiling provides more accurate results.

`pprof(1)`, `setitimer(2)`, `signal(2)`, `sigaction(2)`

Linux 0.99.11, 23 July 1993

ptrace

ptrace—Process trace

SYNOPSIS

```
#include <sys/ptrace.h>
int ptrace(int request,int pid,int addr,int data);
```

DESCRIPTION

`ptrace` provides a means by which a parent process can control the execution of a child process and examine and change its core image. Its primary use is for the implementation of breakpoint debugging. A traced process runs until a signal occurs. Then it stops and the parent is notified with `wait(2)`. When the process is in the stopped state, its memory can be read and written. The parent can also cause the child to continue execution, optionally ignoring the signal which caused stopping.

The value of the request argument determines the precise action of the system call:

<code>PTRACE_TRACEME</code>	This process is to be traced by its parent. The parent should be expecting to trace the child.
<code>PTRACE_PEEKTEXT</code> , <code>PTRACE_PEEKDATA</code>	Read word at location <code>addr</code> .
<code>PTRACE_PEEKUSR</code>	Read word at location <code>addr</code> in the USER area.
<code>PTRACE_POKETEXT</code> , <code>PTRACE_POKEDATA</code>	Write word at location <code>addr</code> .
<code>PTRACE_POKEUSR</code>	Write word at location <code>addr</code> in the USER area.
<code>PTRACE_SYSCALL</code> , <code>PTRACE_CONT</code>	Restart after signal.
<code>PTRACE_KILL</code>	Send the child a <code>SIGKILL</code> to make it exit.
<code>PTRACE_SINGLESTEP</code>	Set the trap flag for single stepping.
<code>PTRACE_ATTACH</code>	Attach to the process specified in <code>pid</code> .
<code>PTRACE_DETACH</code>	Detach a process that was previously attached.

NOTES

init, the process with process ID 1, may not use this function.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

<code>EPERM</code>	The specified process (that is, <code>init</code>), cannot be traced or is already being traced.
<code>ESRCH</code>	The specified process does not exist.
<code>EIO</code>	Request is not valid.

CONFORMS TO

SVID EXT, AT&T, X/OPEN, BSD 4.3

SEE ALSO

`gdb(1)`, `exec(2)`, `signal(2)`, `wait(2)`

quotactl

quotactl—Manipulates disk quotas

SYNOPSIS

```
#include <sys/types.h>
#include <sys/quotactl.h>
int quotactl(int cmd, const char *special, intid, caddr_t addr);
#include <linux/unistd.h>
syscall14(int, quotactl, int, cmd, const char *, special, int, id, caddr_t, addr);
```

DESCRIPTION

The quota system defines for each user or group a soft limit and a hard limit bounding the amount of disk space that can be used on a given filesystem. The hard limit cannot be crossed. The soft limit can be crossed, but warnings will ensue. Moreover, the user cannot be above the soft limit for more than one week (by default) at a time: After this week the soft limit counts as a hard limit.

The `quotactl` system call manipulates these quotas. Its first argument is of the form

```
OCMD(subcmd, type)
```

where `type` is either `USRQUOTA` or `GRPQUOTA` (for user quota and group quota, respectively).

The second argument `special` is the block special device these quotas apply to. It must be mounted.

The third argument `ID` is the user or group ID these quotas apply to (when relevant).

The fourth argument, `addr`, is the address of a data structure, depending on the command.

The `subcmd` is one of the following:

<code>Q_QUOTAON</code>	Enables quotas. The <code>addr</code> argument is the pathname of the file containing the quotas for the filesystem.
<code>Q_QUOTAOFF</code>	Disables quotas.
<code>Q_GETQUOTA</code>	Gets limits and current usage of disk space. The <code>addr</code> argument is a pointer to a <code>dqb1k</code> structure (defined in <code><sys/quotactl.h></code>).
<code>Q_SETQUOTA</code>	Sets limits and current usage; <code>addr</code> is as before.
<code>Q_SETQLIM</code>	Sets limits; <code>addr</code> is as before.
<code>Q_SETUSE</code>	Sets usage.
<code>Q_SYNC</code>	Syncs disk copy of a filesystem's quotas.
<code>Q_GETSTATS</code>	Gets collected stats.

RETURN VALUE

On success, `quotactl` returns 0. On error, -1 is returned and `errno` is set appropriately.

ERRORS

<code>ENOPKG</code>	The kernel was compiled without quota support.
<code>EFAULT</code>	Bad <code>addr</code> value.
<code>EINVAL</code>	<code>type</code> is not a known quota type. Or <code>special</code> could not be found.
<code>ENOTBLK</code>	<code>special</code> is not a block special device.
<code>ENODEV</code>	<code>special</code> cannot be found in the mount table.
<code>EACCES</code>	The quota file is not an ordinary file.
<code>EIO</code>	Cannot read or write the quota file.
<code>EMFILE</code>	Too many open files: Cannot open quota file.

EBUSY	Q_QUOTAON was asked, but quota were enabled already.
ESRCH	Q_GETQUOTA or Q_SETQUOTA or Q_SETUSE or Q_SETQLIM was asked for a filesystem that didn't have quota enabled.
EPERM	The process was not root (for the filesystem), and Q_GETQUOTA was asked for another ID than that of the process itself, or anything other than Q_GETSTATS or Q_SYNC was asked.

read

read—Reads from a file descriptor

SYNOPSIS

```
#include <unistd.h>
ssize_t read(int fd, void* buf, size_t count);
```

DESCRIPTION

`read()` attempts to read up to `count` bytes from file descriptor `fd` into the buffer starting at `buf`.

If `count` is 0, `read()` returns 0 and has no other results. If `count` is greater than `SSIZE_MAX`, the result is unspecified.

RETURN VALUE

On success, the number of bytes read is returned (0 indicates end of file) and the file position is advanced by this number. It is not an error if this number is smaller than the number of bytes requested; this may happen, for example, because fewer bytes are actually available right now (maybe because we were close to end-of-file or because we are reading from a pipe, or from a terminal), or because `read()` was interrupted by a signal. On error, -1 is returned and `errno` is set appropriately. In this case it is left unspecified whether the file position (if any) changes.

ERRORS

EINTR	The call was interrupted by a signal before any data was read.
EAGAIN	Non-blocking I/O has been selected using <code>O_NONBLOCK</code> and no data was immediately available for reading.
EIO	I/O error. This will happen, for example, when the process is in a background process group, tries to read from its controlling <code>tty</code> , and it is ignoring or blocking <code>SIGTTIN</code> or its process group is orphaned.
EISDIR	<code>fd</code> refers to a directory.
EBADF	<code>fd</code> is not a valid file descriptor or is not open for reading.
EINVAL	<code>fd</code> is attached to an object that is unsuitable for reading.
EFAULT	<code>buf</code> is outside your accessible address space.

Other errors may occur, depending on the object connected to `fd`. POSIX allows a read that is interrupted after reading some data to return -1 (with `errno` set to `EINTR`) or to return the number of bytes already read.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

Linux, 17 January 1996

readdir

readdir—Reads directory entry

SYNOPSIS

```
#include <unistd.h>
#include <linux/dirent.h>
#include <linux/unistd.h>
syscall3(int, readdir, uint, fd, struct dirent *, dirp, uint, count);
int readdir(unsigned int fd, struct dirent *dirp, unsigned int count);
```

DESCRIPTION

This is not the function you are interested in. Look at `readdir(3)` for the POSIX-conforming C library interface. This page documents the bare kernel system call interface, which can change, and which is superseded by `getdents(2)`.

`readdir` reads one `dirent` structure from the directory pointed at by `fd` into the memory area pointed to by `dirp`. The parameter `count` is ignored; at most one `dirent` structure is read.

The `dirent` structure is declared as follows:

```
struct dirent
{
    long d_ino;           /* inode number */
    off_t d_off;         /* offset to this dirent */
    unsigned short d_reclen; /* length of this d_name */
    char d_name [NAME_MAX+1]; /* file name (null-terminated) */
}
```

`d_ino` is an inode number. `d_off` is the distance from the start of the directory to this `dirent`. `d_reclen` is the size of `d_name`, not counting the null terminator. `d_name` is a null-terminated filename.

RETURN VALUE

On success, 1 is returned. On end of directory, 0 is returned. On error, -1 is returned and `errno` is set appropriately.

ERRORS

EBADF	Invalid file descriptor <code>fd</code> .
ENOTDIR	File descriptor does not refer to a directory.

CONFORMS TO

This system call is Linux specific.

`getdents(2)`, `readdir(3)`

Linux 1.3.6, 22 July 1995

readlink

readlink—Reads value of a symbolic link

SYNOPSIS

```
#include <unistd.h>
int readlink(const char *path, char *buf, size_t bufsiz);
```

DESCRIPTION

`readlink` places the contents of the symbolic link path in the buffer `buf`, which has size `bufsiz`. `Readlink` does not append a NUL character to `buf`.

RETURN VALUES

The call returns the count of characters placed in the buffer if it succeeds, or a `-1` if an error occurs, placing the error code in the global variable `errno`.

ERRORS

ENOTDIR	A component of the path prefix is not a directory.
EINVAL	The pathname contains a character with the high-order bit set.
ENAMETOOLONG	A component of a pathname exceeded 255 characters, or an entire path name exceeded 1023 characters.
ENOENT	The named file does not exist.
EACCES	Search permission is denied for a component of the path prefix.
ELOOP	Too many symbolic links were encountered in translating the pathname.
EINVAL	The named file is not a symbolic link.
EIO	An I/O error occurred while reading from the filesystem.
EFAULT	<code>buf</code> extends outside the process's allocated address space.

HISTORY

The `readlink` function call appeared in BSD 4.2.

SEE ALSO

`stat(2)`, `lstat(2)`, `symlink(2)`

BSD Man Page, 24 July 1993

readv, writev

`readv, writev`—Reads or writes a vector

SYNOPSIS

```
#include <sys/uio.h>
int readv(int fd, const struct iovec * vector, size_t count);
int writev(int fd, const struct iovec * vector, size_t count);
struct iovec {
    ptr_t iov_base; /* Starting address. */
    size_t iov_len; /* Length in bytes. */
};
```

DESCRIPTION

`readv` reads data from file descriptor `fd` and puts the result in the buffers described by `vector`. The number of buffers is specified by `count`. The buffers are filled in the order specified. Operates just like `read` except that data is put in `vector` instead of a contiguous buffer.

`writev` writes data to file descriptor `fd`, and from the buffers described by `vector`. The number of buffers is specified by `count`. The buffers are used in the order specified. Operates just like `write` except that data is taken from `vector` instead of a contiguous buffer.

RETURN VALUE

On success, `readv` returns the number of bytes read. On success, `writev` returns the number of bytes written. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

EINVAL	An invalid argument was given. For instance <code>count</code> might be greater than <code>MAX_IOVEC</code> , or <code>0</code> . <code>fd</code> could also be attached to an object that is unsuitable for reading.
EFAULT	Segmentation fault. Most likely <code>vector</code> or some of the <code>iov_base</code> pointers points to memory that is not properly allocated.
EBADF	The file descriptor <code>fd</code> is not valid.
EINTR	The call was interrupted by a signal before any data was read/written.
EAGAIN	Non-blocking I/O has been selected using <code>O_NONBLOCK</code> and no data was immediately available for reading. (Or the file descriptor <code>fd</code> is for an object that is locked.)
EISDIR	<code>fd</code> refers to a directory.
EOPNOTSUPP	<code>fd</code> refers to a socket or device that does not support reading/writing.

Other errors may occur, depending on the object connected to `fd`.

Linux 1.3.86, 12 April 1996

reboot

`reboot`—Reboots or disables Ctrl+Alt+Del

SYNOPSIS

```
#include <unistd.h>
int reboot (int magic, int magic_too, int flag);
```

DESCRIPTION

`reboot` reboots the system or enables/disables CAD.

If `magic = 0xf00dead` and `magic_too = 672274793`, the action performed will be based on `flag`.

If `flag=0x1234567`, a hard reset is performed.

If `flag=0x89abcdef`, CAD is enabled.

If `flag=0`, CAD is disabled and a signal is sent to process ID 1.

Note that `reboot()` does *not* `sync()`!

Only the superuser may use this function.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

EINVAL	Bad <code>magic</code> numbers or <code>flag</code> .
EPERM	A non-root user has attempted to call <code>reboot</code> .

CONFORMS TO

reboot is Linux specific.

recv, recvfrom, recvmsg

recv, recvfrom, recvmsg—Receives a message from a socket

SYNOPSIS

```
#include <sys/types.h>
#include <sys/socket.h>
int recv(int s, void *buf, int len, unsigned int flags);
int recvfrom(int s, void*buf, int len, unsigned int flags,
             struct sockaddr *from, int *fromlen);
int recvmsg(int s, struct msghdr *msg, unsigned int flags);
```

DESCRIPTION

Warning: This is a BSD man page. As of Linux 0.99.11, `recvmsg` was not implemented.

`recvfrom` and `recvmsg` are used to receive messages from a socket, and may be used to receive data on a socket whether or not it is connection oriented.

If `from` is non-nil, and the socket is not connection-oriented, the source address of the message is filled in. `fromlen` is a value-result parameter, initialized to the size of the buffer associated with `from` and modified on return to indicate the actual size of the address stored there.

The `recv` call is normally used only on a connected socket (see `connect(2)`) and is identical to `recvfrom` with a nil `from` parameter. Because it is redundant, it might not be supported in future releases.

All three routines return the length of the message on successful completion. If a message is too long to fit in the supplied buffer, excess bytes might be discarded depending on the type of socket from which the message is received (see `socket(2)`).

If no messages are available at the socket, the receive call waits for a message to arrive—unless the socket is nonblocking (see `fcntl(2)`), in which case the value `-1` is returned and the external variable `errno` is set to `EWOULDBLOCK`. The receive calls normally return any data available, up to the requested amount, rather than wait for receipt of the full amount requested; this behavior is affected by the socket-level options `SO_RCVLOWAT` and `SO_RCVTIMEO`, described in `getsockopt(2)`.

The `select(2)` call may be used to determine when more data arrives.

The `flags` argument to a `recv` call is formed by oring one or more of the values:

MSG_OOB	Process out-of-band data
MSG_PEEK	Peek at incoming message
MSG_WAITALL	Wait for full request or error

The `MSG_OOB` flag requests receipt of out-of-band data that would not be received in the normal data stream. Some protocols place expedited data at the head of the normal data queue; thus this flag cannot be used with such protocols. The `MSG_PEEK` flag causes the receive operation to return data from the beginning of the receive queue without removing that data from the queue; thus, a subsequent receive call will return the same data. The `MSG_WAITALL` flag requests that the operation block until the full request is satisfied. However, the call might still return less data than requested if a signal is caught, an error or disconnect occurs, or the next data to be received is of a different type than that returned.

The `recvmsg` call uses a `msg_hdr` structure to minimize the number of directly supplied parameters. This structure has the following form, as defined in `sys/socket.h`:

```
struct msg_hdr {
    caddr_t msg_name; /* optional address */
    u_int msg_namelen; /* size of address */
    struct iovec *msg_iov; /* scatter/gather array */
    u_int msg_iovlen; /* # elements in msg_iov */
    caddr_t msg_control; /* ancillary data, see below */
    u_int msg_controllen; /* ancillary data buffer len */
    int msg_flags; /* flags on received message */
};
```

Here `msg_name` and `msg_namelen` specify the destination address if the socket is unconnected; `msg_name` may be given as a null pointer if no names are desired or required. `msg_iov` and `msg_iovlen` describe scatter gather locations, as discussed in `read(2)`. `msg_control`, which has length `msg_controllen`, points to a buffer for other protocol control-related messages or other miscellaneous ancillary data. The messages are of the form

```
struct cmsghdr {
    u_int cmsg_len; /* data byte count, including hdr */
    int cmsg_level; /* originating protocol */
    int cmsg_type; /* protocol-specific type */
    /* followed by
    u_char cmsg_data[]; */
};
```

You could use this, for example, to learn of changes in the data stream in XNS/SPP, or in ISO, to obtain user-connection-request data by requesting a `recvmsg` with no data buffer provided immediately after an `accept` call.

Open file descriptors are now passed as ancillary data for `AF_UNIX` domain sockets, with `cmsg_level` set to `SOL_SOCKET` and `cmsg_type` set to `SCM_RIGHTS`.

The `msg_flags` field is set on return according to the message received. `MSG_EOR` indicates end-of-record; the data returned completed a record (generally used with sockets of type `SOCK_SEQPACKET`). `MSG_TRUNC` indicates that the trailing portion of a datagram was discarded because the datagram was larger than the buffer supplied. `MSG_CTRUNC` indicates that some control data was discarded due to lack of space in the buffer for ancillary data. `MSG_OOB` is returned to indicate that expedited or out-of-band data was received.

RETURN VALUES

These calls return the number of bytes received, or `-1` if an error occurred.

ERRORS

<code>EBADF</code>	The argument <code>s</code> is an invalid descriptor.
<code>ENOTCONN</code>	The socket is associated with a connection-oriented protocol and has not been connected (see <code>connect(2)</code> and <code>accept(2)</code>).
<code>ENOTSOCK</code>	The argument <code>s</code> does not refer to a socket.
<code>EWOULDBLOCK</code>	The socket is marked non-blocking, and the receive operation would block, or a receive timeout had been set, and the timeout expired before data was received.
<code>EINTR</code>	The receive was interrupted by delivery of a signal before any data was available.
<code>EFAULT</code>	The receive buffer pointer(s) point outside the process's address space.

HISTORY

These function calls appeared in BSD 4.2.

BSD Man Page, 24 July 1993

rename

`rename`—Changes the name or location of a file

SYNOPSIS

```
#include <unistd.h>
int rename(const char *oldpath, const char *newpath);
```

DESCRIPTION

`rename` renames a file, moving it between directories if required.

Any other hard links to the file (as created using `link`) are unaffected.

If `newpath` already exists it will be automatically overwritten (subject to a few conditions—see the “Errors” section), so that there is no point at which another process attempting to access `newpath` will find it missing.

If `newpath` exists but the operation fails for some reason or the system crashes, `rename` guarantees to leave an instance of `newpath` in place.

However, when overwriting there will probably be a window in which both `oldpath` and `newpath` refer to the file being renamed.

If `oldpath` refers to a symbolic link, the link will be renamed; if `newpath` refers to a symbolic link, the link will be overwritten.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

EISDIR	<code>newpath</code> is an existing directory, but <code>oldpath</code> is not a directory.
EXDEV	<code>oldpath</code> and <code>newpath</code> are not on the same filesystem.
ENOTEMPTY	<code>newpath</code> is a non-empty directory.
EBUSY	<code>newpath</code> exists and is the current working directory or root directory of some process.
EINVAL	An attempt was made to make a directory a subdirectory of itself.
EMLINK	<code>oldpath</code> already has the maximum number of links to it, or it was a directory and the directory containing <code>newpath</code> has the maximum number of links.
ENOTDIR	A component used as a directory in <code>oldpath</code> or <code>newpath</code> is not, in fact, a directory.
EFAULT	<code>oldpath</code> or <code>newpath</code> points outside your accessible address space.
EACCES	Write access to the directory containing <code>oldpath</code> or <code>newpath</code> is not allowed for the process’s effective UID, or one of the directories in <code>oldpath</code> or <code>newpath</code> did not allow search (execute) permission, or <code>oldpath</code> was a directory and did not allow write permission (needed to update the <code>..</code> entry).
EPERM	The directory containing <code>oldpath</code> has the sticky bit set, and the process’s effective UID is neither the UID of the file to be deleted nor that of the directory containing it, or the filesystem containing <code>pathname</code> does not support renaming of the type requested.
ENAMETOOLONG	<code>oldpath</code> or <code>newpath</code> was too long.
ENOENT	A directory component in <code>oldpath</code> or <code>newpath</code> does not exist or is a dangling symbolic link.
ENOMEM	Insufficient kernel memory was available.
EROFS	The file is on a read-only filesystem.

ELOOP `ol dpath` or `newpath` contains a reference to a circular symbolic link; that is, a symbolic link whose expansion contains a reference to itself.

ENOSPC The device containing the file has no room for the new directory entry.

CONFORMS TO

POSIX, BSD 4.3, ANSI C

BUGS

Currently (Linux 0.99pl7), most of the filesystems except Minix will not allow any overwriting renames involving directories. You get **EEXIST** if you try.

On NFS filesystems, you cannot assume that just because the operation failed, the file was not renamed. If the server does the rename operation and then crashes, the retransmitted RPC, which will be processed when the server is up again, causes a failure. The application is expected to deal with this. See `link(2)` for a similar problem.

SEE ALSO

`link(2)`, `unlink(2)`, `symlink(2)`, `mv(1)`, `link(8)`

Linux 0.99.7, 24 July 1993

rmdir

`rmdir`—Deletes a directory

SYNOPSIS

```
#include <unistd.h>
int rmdir(const char *pathname);
```

DESCRIPTION

`rmdir` deletes a directory, which must be empty.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

EPERM The filesystem containing `pathname` does not support the removal of directories.

EFAULT `pathname` points outside your accessible address space.

EACCES Write access to the directory containing `pathname` was not allowed for the process's effective UID, or one of the directories in `pathname` did not allow search (execute) permission.

EPERM The directory containing `pathname` has the sticky bit (`S_ISVTX`) set, and the process's effective UID is neither the UID of the file to be deleted nor that of the directory containing it.

ENAMETOOLONG `pathname` was too long.

ENOENT A directory component in `pathname` does not exist or is a dangling symbolic link.

ENOTDIR `pathname`, or a component used as a directory in `pathname`, is not, in fact, a directory.

ENOTEMPTY `pathname` contains entries other than `.` and `...`

EBUSY `pathname` is the current working directory or root directory of some process.

ENOMEM Insufficient kernel memory was available.

EROFS `pathname` refers to a file on a read-only filesystem.

ELOOP `pathname` contains a reference to a circular symbolic link; that is, a symbolic link containing a reference to itself.

CONFORMS TO

SVID, AT&T, POSIX, BSD 4.3

BUGS

Inelicities in the protocol underlying NFS can cause the unexpected disappearance of directories that are still being used.

Linux 0.99.7, 24 July 1993

`sched_get_priority_max`, `sched_get_priority_min`

`sched_get_priority_max`, `sched_get_priority_min`—Gets static priority range

SYNOPSIS

```
#include <sched.h>
int sched_get_priority_max(int policy);
int sched_get_priority_min(int policy);
```

DESCRIPTION

`sched_get_priority_max` returns the maximum priority value that can be used with the scheduling algorithm identified by `policy`. `sched_get_priority_min` returns the minimum priority value that can be used with the scheduling algorithm identified by `policy`. **Supported `policy` values** are `SCHED_FIFO`, `SCHED_RR`, and `SCHED_OTHER`.

Processes with numerically higher priority values are scheduled before processes with numerically lower priority values. Therefore, the value returned by `sched_get_priority_max` will be greater than the value returned by `sched_get_priority_min`.

Linux allows the static priority value range 1 to 99 for `SCHED_FIFO` and `SCHED_RR`, and the priority 0 for `SCHED_OTHER`. Scheduling priority ranges for the various policies are not alterable.

The range of scheduling priorities may vary on other POSIX systems, so it is a good idea for portable applications to use a virtual priority range and map it to the interval given by `sched_get_priority_max` and `sched_get_priority_min`. POSIX.1b requires a spread of at least 32 between the maximum and the minimum values for `SCHED_FIFO` and `SCHED_RR`.

POSIX systems on which `sched_get_priority_max` and `sched_get_priority_min` are available define `_POSIX_PRIORITY_SCHEDULING` in `<unistd.h>`.

RETURN VALUE

On success, `sched_get_priority_max` and `sched_get_priority_min` return the maximum and minimum priority values for the named scheduling policy. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

`EINVAL` The parameter `policy` does not identify a defined scheduling policy.

STANDARDS

POSIX.1b (formerly POSIX.4)

Linux 1.3.81, 10 April 1996

sched_rr_get_interval

sched_rr_get_interval—Gets the SCHED_RR interval for the named process

SYNOPSIS

```
#include <sched.h>
int sched_rr_get_interval(pid_t pid, struct timespec *tp);
struct timespec {
    time_t tv_sec; /* seconds */
    long tv_nsec; /* nanoseconds */
};
```

DESCRIPTION

sched_rr_get_interval writes into the `timespec` structure pointed to by `tp` the round-robin time quantum for the process identified by `pid`. If `pid` is 0, the time quantum for the calling process is written into `*tp`. The identified process should be running under the SCHED_RR scheduling policy.

The round robin time quantum value is not alterable under Linux 1.3.81.

POSIX systems on which `sched_rr_get_interval` is available define `_POSIX_PRIORITY_SCHEDULING` in `<unistd.h>`.

RETURN VALUE

On success, `sched_rr_get_interval` returns 0. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

ESRCH	The process whose ID is <code>pid</code> could not be found.
ENOSYS	The system call is not yet implemented.

STANDARDS

POSIX.1b (formerly POSIX.4)

BUGS

As of Linux 1.3.81, `sched_rr_get_interval` returns with error `ENOSYS`, because `SCHED_RR` has not yet been fully implemented or tested properly.

SEE ALSO

`sched_setscheduler(2)` has a description of the Linux scheduling scheme.

sched_setparam, sched_getparam

sched_setparam, sched_getparam—Sets and get scheduling parameters

SYNOPSIS

```
#include <sched.h>
int sched_setparam(pid_t pid, const struct sched_param *p);
int sched_getparam(pid_t pid, struct sched_param *p);
struct sched_param {
    ...
    int sched_priority;
    ...
};
```

DESCRIPTION

sched_setparam sets the scheduling parameters associated with the scheduling policy for the process identified by `pid`. If `pid` is 0, the parameters of the current process are set. The interpretation of the parameter `p` depends on the selected policy. Currently, the following three scheduling policies are supported under Linux: SCHED_FIFO, SCHED_RR, and SCHED_OTHER.

sched_getparam retrieves the scheduling parameters for the process identified by `pid`. If `pid` is 0, the parameters of the current process are retrieved.

sched_setparam checks the validity of `p` for the scheduling policy of the process. The parameter `p->sched_priority` must lie within the range given by `sched_get_priority_min` and `sched_get_priority_max`.

POSIX systems on which `sched_setparam` and `sched_getparam` are available define `_POSIX_PRIORITY_SCHEDULING` in `<unistd.h>`.

RETURN VALUE

On success, `sched_setparam` and `sched_getparam` return 0. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

ESRCH	The process whose ID is <code>pid</code> could not be found.
EPERM	The calling process does not have appropriate privileges. The process calling <code>sched_setparam</code> needs an effective UID equal to the UID or UID of the process identified by <code>pid</code> , or it must be a superuser process.
EINVAL	The parameter <code>p</code> does not make sense for the current scheduling policy.

STANDARDS

POSIX.1b (formerly POSIX.4)

ISO/IEC 9945-1:1996

sched_setscheduler, sched_getscheduler

sched_setscheduler, sched_getscheduler—Sets and gets scheduling algorithm/parameters

SYNOPSIS

```
#include <sched.h>
int sched_setscheduler(pid_t pid, int policy, const struct sched_param *p);
int sched_getscheduler(pid_t pid);
struct sched_param {
    ...
    int sched_priority;
    ...
};
```

DESCRIPTION

`sched_setscheduler` sets both the scheduling policy and the associated parameters for the process identified by `pid`. If `pid` is 0, the scheduler of the calling process will be set. The interpretation of the parameter `p` depends on the selected policy.

Currently, the following three scheduling policies are supported under Linux: `SCHED_FIFO`, `SCHED_RR`, and `SCHED_OTHER`; their respective semantics are described in the following section.

`sched_getscheduler` queries the scheduling policy currently applied to the process identified by `pid`. If `pid` is 0, the policy of the calling process will be retrieved.

SCHEDULING POLICIES

The scheduler is the kernel part that decides which runnable process will be executed next by the CPU. The Linux scheduler offers three different scheduling policies, one for normal processes and two for real-time applications. A static priority value, `sched_priority`, is assigned to each process, and this value can be changed only via system calls. Conceptually, the scheduler maintains a list of runnable processes for each possible `sched_priority` value, and `sched_priority` can have a value in the range 0 to 99. To determine the process that runs next, the Linux scheduler looks for the non-empty list with the highest static priority and takes the process at the head of this list. The scheduling policy determines, for each process, where it will be inserted into the list of processes with equal static priority and how it will move inside this list.

`SCHED_OTHER` is the default universal time-sharing scheduler policy used by most processes; `SCHED_FIFO` and `SCHED_RR` are intended for special, time-critical applications that need precise control over the way in which runnable processes are selected for execution. Processes scheduled with `SCHED_OTHER` must be assigned the static priority 0; processes scheduled under `SCHED_FIFO` or `SCHED_RR` can have a static priority in the range 1 to 99. Only processes with superuser privileges can get a static priority higher than 0 and can therefore be scheduled under `SCHED_FIFO` or `SCHED_RR`. The system calls `sched_get_priority_min` and `sched_get_priority_max` can be used to find out the valid priority range for a scheduling policy in a portable way on all POSIX.1b-conforming systems.

All scheduling is preemptive: If a process with a higher static priority gets ready to run, the current process will be preempted and returned into its wait list. The scheduling policy determines the ordering within the list of runnable processes only among those with equal static priority.

SCHED_FIFO: FIRST IN-FIRST OUT SCHEDULING

`SCHED_FIFO` can only be used with static priorities higher than 0, which means that when a `SCHED_FIFO` process becomes runnable, it will always preempt immediately any currently running normal `SCHED_OTHER` process. `SCHED_FIFO` is a simple scheduling algorithm without time slicing.

For processes scheduled under the `SCHED_FIFO` policy, the following rules are applied: A `SCHED_FIFO` process that has been preempted by another process of higher priority will stay at the head of the list for its priority and will resume execution as soon as all processes of higher priority are blocked again. When a `SCHED_FIFO` process becomes runnable, it will be inserted at the end of the list for its priority. A call to `sched_setscheduler` or `sched_setparam` will put the `SCHED_FIFO` process identified by

`pid` at the end of the list if it was runnable. A process calling `sched_yield` will be put at the end of the list. No other events will move a process scheduled under the `SCHED_FIFO` policy in the wait list of runnable processes with equal static priority. A `SCHED_FIFO` process runs until it is blocked by an I/O request, it is preempted by a higher-priority process, or it calls `sched_yield`.

SCHED_RR: ROUND-ROBIN SCHEDULING

`SCHED_RR` is a simple enhancement of `SCHED_FIFO`. Everything described in the preceding section for `SCHED_FIFO` also applies to `SCHED_RR`, except that each process is only allowed to run for a maximum time quantum. If a `SCHED_RR` process has been running for a time period equal to or longer than the time quantum, it will be put at the end of the list for its priority. A `SCHED_RR` process that has been preempted by a higher-priority process and subsequently resumes execution as a running process will complete the unexpired portion of its round-robin time quantum. The length of the time quantum can be retrieved by `sched_rr_get_interval`.

SCHED_OTHER: DEFAULT LINUX TIME-SHARING SCHEDULING

`SCHED_OTHER` can only be used at static priority 0. `SCHED_OTHER` is the standard Linux time-sharing scheduler that is intended for all processes that do not require special static-priority real-time mechanisms. The process to run is chosen from the static priority 0 list based on a dynamic priority that is determined only inside this list. The dynamic priority is based on the nice level (set by the `nice` or `setpriority` system call) and is increased for each time quantum the process is ready to run but is denied to run by the scheduler. This ensures fair progress among all `SCHED_OTHER` processes.

RESPONSE TIME

A blocked high-priority process waiting for the I/O has a certain response time before it is scheduled again. The device driver writer can greatly reduce this response time by using a *slow interrupt* interrupt handler, as described in `request_irq(9)`.

MISCELLANEOUS

Child processes inherit the scheduling algorithm and parameters across a `fork`.

Memory locking is usually needed for real-time processes to avoid paging delays; this can be done with `mlock` or `mlockall`.

Because a non-blocking endless loop in a process scheduled under `SCHED_FIFO` or `SCHED_RR` will block all processes with lower priority forever, a software developer should always keep available on the console a shell scheduled under a higher static priority than the tested application. This will allow an emergency kill of tested real-time applications that do not block or terminate as expected. Because `SCHED_FIFO` and `SCHED_RR` processes can preempt other processes forever, only root processes are allowed to activate these policies under Linux.

POSIX systems on which `sched_setscheduler` and `sched_getscheduler` are available define `_POSIX_PRIORITY_SCHEDULING` in `<unistd.h>`.

RETURN VALUE

On success, `sched_setscheduler` returns 0. On success, `sched_getscheduler` returns the policy for the process (a non-negative integer). On error, -1 is returned, and `errno` is set appropriately.

ERRORS

ESRCH	The process whose ID is <code>pid</code> could not be found.
EPERM	The calling process does not have appropriate privileges. Only root processes are allowed to activate the <code>SCHED_FIFO</code> and <code>SCHED_RR</code> policies. The process calling <code>sched_setscheduler</code> needs an effective UID equal to the EUID or UID of the process identified by <code>pid</code> , or it must be a superuser process.
EINVAL	The scheduling policy is not one of the recognized policies, or the parameter <code>p</code> does not make sense for the policy.

STANDARDS

POSIX.1b (formerly POSIX.4)

BUGS

As of Linux 1.3.81, SCHED_RR has not yet been tested carefully and might not behave exactly as described or required by POSIX.1b.

sched_yield

sched_yield—Yields the processor

SYNOPSIS

```
#include <sched.h>
int sched_yield(void);
```

DESCRIPTION

A process can relinquish the processor voluntarily without blocking by calling `sched_yield`. The process will then be moved to the end of the queue for its static priority and a new process gets to run.

Note: If the current process is the only process in the highest priority list at that time, this process will continue to run after a call to `sched_yield`.

POSIX systems on which `sched_yield` is available define `_POSIX_PRIORITY_SCHEDULING` in `<unistd.h>`.

RETURN VALUE

On success, `sched_yield` returns 0. On error, -1 is returned, and `errno` is set appropriately.

select, FD_CLR, FD_ISSET, FD_SET, FD_ZERO

select, FD_CLR, FD_ISSET, FD_SET, FD_ZERO—Synchronous I/O multiplexing

SYNOPSIS

```
#include <sys/time.h>
#include <sys/types.h>
#include <unistd.h>
int select(int n,fd_set *readfds,fd_set *writefds,fd_set *exceptfds,
    struct timeval *timeout);
FD_CLR(int fd,fd_set *set);
FD_ISSET(int fd,fd_set *set);
FD_SET(int fd,fd_set *set);
FD_ZERO(fd_set *set)
```

DESCRIPTION

`select` waits for a number of file descriptors to change status.

Three independent sets of descriptors are watched. Those listed in `readfds` will be watched to see if characters become available for reading, those in `writefds` will be watched to see if it is okay to immediately write on them, and those in `exceptfds` will be watched for exceptions. On exit, the sets are modified in place to indicate which descriptors actually changed status.

Four macros are provided to manipulate the sets. `FD_ZERO` will clear a set. `FD_SET` and `FD_CLR` add or remove a given descriptor from a set. `FD_ISSET` tests to see if a descriptor is part of the set; this is useful after `select` returns.

`n` is the highest-numbered descriptor in any of the three sets, plus 1.

`timeout` is an upper bound on the amount of time elapsed before `select` returns. It may be 0, which causes `select` to return immediately. If `timeout` is NULL (no timeout), `select` can block indefinitely.

RETURN VALUE

On success, `select` returns the number of descriptors contained in the descriptor sets, which may be 0 if the timeout expires before anything interesting happens. On error, -1 is returned, and `errno` is set appropriately; the sets and `timeout` become undefined, so do not rely on their contents after an error.

ERRORS

EBAADF	An invalid file descriptor was given in one of the sets.
EINTR	A non-blocked signal was caught.
EINVAL	<code>n</code> is negative.
ENOMEM	<code>select</code> was unable to allocate memory for internal tables.

NOTES

Some code calls `select` with all three sets empty, `n=0`, and a non-null timeout; this is a fairly portable way to sleep with subsecond precision.

On Linux, `timeout` is modified to reflect the amount of time not slept; most other implementations do not do this. This causes problems both when Linux code that reads `timeout` is ported to other operating systems and when code is ported to Linux that reuses a `struct timeval` for multiple `select`s in a loop without reinitializing it. Consider `timeout` to be undefined after `select` returns.

EXAMPLE

```
#include <stdio.h>
#include <sys/time.h>
#include <sys/types.h>
#include <unistd.h>
```

```

int
main(void)
{
    fd_set rfds;
    struct timeval tv;
    int retval;

    /* Watch stdin (fd 0) to see when it has input. */
    FD_ZERO(&rfds);
    FD_SET(0, &rfds);
    /* Wait up to five seconds. */
    tv.tv_sec = 5;
    tv.tv_usec = 0;

    retval = select(1, &rfds, NULL, NULL, &tv);
    /* Don't rely on the value of tv now! */

    if (retval)
        printf("Data is available now.nn");
        /* FD_ISSET(0, &rfds) will be true. */
    else
        printf("No data within five seconds.nn");
    exit(0);
}

```

semctl

semctl—Semaphore-control operations

SYNOPSIS

```

#include <sys/types.h>
#include <sys/ipc.h>
#include <sys/sem.h>
int semctl ( int semid,int semnum,int cmd, union semun arg );

```

DESCRIPTION

The function performs the control operation specified by `cmd` on the semaphore set (or on the `sumun`-nth semaphore of the set) identified by `semid`. The first semaphore of the set is indicated by a value of 0 for `semun`.

The type of `arg` is the union

```

union semun {
    int val; /* used for SETVAL only */
    struct semid_ds *buf; /* for IPC_STAT and IPC_SET */
    ushort *array; /* used for GETALL and SETALL */
};

```

Legal values for `cmd` are

`IPC_STAT` Copies info from the semaphore set data structure into the structure pointed to by `arg.buf`. The argument `semnum` is ignored. The calling process must have read access privileges on the semaphore set.

IPC_SET	Writes the values of some members of the <code>semid_ds</code> structure pointed to by <code>arg.buf</code> to the semaphore set data structure, updating also its <code>sem_ctime</code> member. Considered members from the user-supplied struct <code>semid_ds</code> pointed to by <code>arg.buf</code> are <code>sem_perm.uid</code> <code>sem_perm.gid</code> <code>sem_perm.mode /* only lowest 9-bits */</code> The calling process's effective user ID must be super-user, creator, or owner of the semaphore set. The argument <code>semnum</code> is ignored.
IPC_RMID	Removes the semaphore set and its data structures immediately, awakening all waiting processes (with an error return and <code>errno</code> set to <code>EIDRM</code>). The calling process's effective user ID must be super-user, creator, or owner of the semaphore set. The argument <code>semnum</code> is ignored.
GETALL	Returns <code>semval</code> for all semaphores of the set into <code>arg.array</code> . The argument <code>semnum</code> is ignored. The calling process must have read access privileges on the semaphore set.
GETNCNT	The system call returns the value of <code>semncnt</code> for the <code>semno</code> -th semaphore of the set (that is, the number of processes waiting for an increase of <code>semval</code> for the <code>semno</code> -th semaphore of the set). The calling process must have read access privileges on the semaphore set.
GETPID	The system call returns the value of <code>sempid</code> for the <code>semno</code> -th semaphore of the set (that is, the <code>pid</code> of the process that executed the last <code>semop</code> call for the <code>semno</code> -th semaphore of the set). The calling process must have read access privileges on the semaphore set.
GETVAL	The system call returns the value of <code>semval</code> for the <code>semno</code> -th semaphore of the set. The calling process must have read access privileges on the semaphore set.
GETZCNT	The system call returns the value of <code>semzcnt</code> for the <code>semno</code> -th semaphore of the set (that is, the number of processes waiting for the <code>semval</code> of the <code>semno</code> -th semaphore of the set to become 0). The calling process must have read access privileges on the semaphore set.
SETALL	Sets <code>semval</code> for all semaphores of the set using <code>arg.array</code> , updating also the <code>sem_ctime</code> member of the <code>semid_ds</code> structure associated with the set. Undo entries are cleared for altered semaphores in all processes. Processes sleeping on the wait queue are awakened if some <code>semval</code> becomes 0 or increases. The argument <code>semnum</code> is ignored. The calling process must have alter access privileges on the semaphore set.
SETVAL	Sets the value of <code>semval</code> to <code>arg.val</code> for the <code>semnum</code> -th semaphore of the set, updating also the <code>sem_ctime</code> member of the <code>semid_ds</code> structure associated to the set. The undo entry is cleared for the altered semaphore in all processes. Processes sleeping on the wait queue are awakened if <code>semval</code> becomes 0 or increases. The calling process must have alter access privileges on the semaphore set.

RETURN VALUE

On fail, the system call returns -1, with `errno` indicating the error. Otherwise the system call returns a non-negative value, depending on `cmd`, as follows:

GETNCNT	The value of <code>semncnt</code> .
GETPID	The value of <code>sempid</code> .
GETVAL	The value of <code>semval</code> .
GETZCNT	The value of <code>semzcnt</code> .

ERRORS

For a failing return, `errno` will be set to one of the following values:

EACCESS	The calling process has no access permissions needed to execute <code>cmd</code> .
EFAULT	The address pointed to by <code>arg.buf</code> or <code>arg.array</code> isn't accessible.
EIDRM	The semaphore set was removed.
EINVAL	Invalid value for <code>cmd</code> or <code>semi d</code> .

EPERM	The argument <code>cmd</code> has the value <code>IPC_SET</code> or <code>IPC_RMID</code> , but the calling process's effective user ID has insufficient privileges to execute the command.
ERANGE	The argument <code>cmd</code> has the value <code>SETALL</code> or <code>SETVAL</code> , and the value to which <code>semval</code> has to be set (for some semaphore of the set) is less than 0 or greater than the implementation value <code>SEMVMX</code> .

NOTES

The `IPC_INFO`, `SEM_STAT`, and `SEM_INFO` control calls are used by the `ipcs(1)` program to provide information on allocated resources. In the future these can be modified as needed or moved to a `proc` filesystem interface.

The following system limit on semaphore sets affects a `semctl` call:

`SEMVMX` Maximum value for `semval`; implementation dependent (32767).

semget

`semget`—Gets a semaphore set identifier

SYNOPSIS

```
# include <sys/types.h>
# include <sys/ipc.h>
# include <sys/sem.h>
int semget ( key_t key, int nsems, int semflg );
```

DESCRIPTION

This function returns the semaphore set identifier associated with the value of the argument `key`. A new set of `nsems` semaphores is created if `key` has the value `IPC_PRIVATE` or `key` isn't `IPC_PRIVATE`, if no existing message queue is associated to `key`, and if `IPC_CREAT` is asserted in `semflg` (that is, `semflg & IPC_CREAT` isn't 0). The presence in `semflg` of the fields `IPC_CREAT` and `IPC_EXCL` plays the same role, with respect to the existence of the semaphore set, as the presence of `O_CREAT` and `O_EXCL` in the `mode` argument of the `open(2)` system call—that is, the `msgget` function fails if `semflg` asserts both `IPC_CREAT` and `IPC_EXCL` and a semaphore set already exists for `key`.

Upon creation, the lower 9 bits of the argument `semflg` define the access permissions (for owner, group, and others) to the semaphore set in the same format, and with the same meaning, as for the access permissions parameter in the `open(2)` or `creat(2)` system call (although the execute permissions are not used by the system, and the term *write permissions*, for a semaphore set, effectively means *alter permissions*).

Furthermore, while creating, the system call initializes the system semaphore set data structure `semid_ds` as follows:

- `sem_perm.cuid` and `sem_perm.uid` are set to the effective user ID of the calling process.
- `sem_perm.cgid` and `sem_perm.gid` are set to the effective group ID of the calling process.
- The lowest-order 9 bits of `sem_perm.mode` are set to the lowest-order 9 bits of `semflg`.
- `sem_nsems` is set to the value of `nsems`.
- `sem_otime` is set to 0.
- `sem_ctime` is set to the current time.

The argument `nsems` can be 0 (a “don't care”) when the system call isn't `create(2)`. Otherwise, `nsems` must be greater than 0 and less or equal to the maximum number of semaphores per `semid` (`SEMMSL`).

If the semaphore set already exists, the access permissions are verified, and a check is made to see if it is marked for destruction.

RETURN VALUE

If successful, the return value will be the semaphore set identifier (a positive integer); otherwise it will be `-1`, with `errno` indicating the error.

ERRORS

For a failing return, `errno` will be set to one of the following values:

<code>EACCESS</code>	A semaphore set exists for <code>key</code> , but the calling process has no access permissions to the set.
<code>EEXIST</code>	A semaphore set exists for <code>key</code> , and <code>semflg</code> was asserting both <code>IPC_CREAT</code> and <code>IPC_EXCL</code> .
<code>EIDRM</code>	The semaphore set is marked to be deleted.
<code>ENOENT</code>	No semaphore set exists for <code>key</code> , and <code>semflg</code> wasn't asserting <code>IPC_CREAT</code> .
<code>ENOMEM</code>	A semaphore set has to be created, but the system does not have enough memory for the new data structure.
<code>ENOSPC</code>	A semaphore set has to be created, but the system limit for the maximum number of semaphore sets (<code>SEMMNI</code>) or the system-wide maximum number of semaphores (<code>SEMMNS</code>) would be exceeded.

NOTES

`IPC_PRIVATE` isn't a flag field but a `key_t` type. If this special value is used for `key`, the system call ignores everything but the lowest-order 9 bits of `semflg` and creates a new semaphore set (on success).

The followings are limits on semaphore set resources affecting a `semget` call:

<code>SEMMNI</code>	System-wide maximum number of semaphore sets; policy dependent.
<code>SEMMSL</code>	Maximum number of semaphores per <code>semid</code> ; implementation dependent (500 currently).
<code>SEMMNS</code>	System-wide maximum number of semaphores; policy dependent. A value greater than <code>SEMMSL × SEMMNI</code> makes it irrelevant.

BUGS

Use of `IPC_PRIVATE` doesn't inhibit other processes' access to the allocated semaphore set.

As for the files, there is currently no intrinsic way for a process to ensure exclusive access to a semaphore set. Asserting both `IPC_CREAT` and `IPC_EXCL` in `semflg` only ensures (on success) that a new semaphore set will be created; it doesn't imply exclusive access to the semaphore set.

The data structure associated with each semaphore in the set isn't initialized by the system call. In order to initialize those data structures, you have to execute a subsequent call to `semctl(2)` to perform a `SETVAL` or a `SETALL` command on the semaphore set.

`ftok(3)`, `ipc(5)`, `semctl(2)`, `semop(2)`

Linux 0.99.13, 1 November 1993

semop

`semop`—Semaphore operations

SYNOPSIS

```
# include <sys/types.h>
# include <sys/ipc.h>
# include <sys/sem.h>
int semop ( int semid, struct sembuf *sops, unsigned nsops );
```

DESCRIPTION

The function performs operations on selected members of the semaphore set indicated by `semi d`. Each of the `nsops` elements in the array pointed to by `sops` specifies an operation to be performed on a semaphore by a struct `sembuf` including the following members:

```
short sem_num; /* semaphore number: 0 = first */
short sem_op; /* semaphore operation */
short sem_flg; /* operation flags */
```

Flags recognized in `sem_flg` are `IPC_NOWAIT` and `SEM_UNDO`. If an operation asserts `SEM_UNDO`, it will be undone when the process exits.

The system call semantic assures that the operations will be performed if and only if all of them will succeed. Each operation is performed on the `sem_num`-th semaphore of the semaphore set, where the first semaphore of the set is semaphore 0 and is one of the following three:

- If `sem_op` is a positive integer, the operation adds this value to `semval`. Furthermore, if `SEM_UNDO` is asserted for this operation, the system updates the process undo count for this semaphore. The operation always goes through, so no process sleeping can happen. The calling process must have alter permissions on the semaphore set.
- If `sem_op` is 0, the process must have read access permissions on the semaphore set. If `semval` is 0, the operation goes through. Otherwise, if `IPC_NOWAIT` is asserted in `sem_flg`, the system call fails (undoing all previous actions performed), with `errno` set to `EAGAIN`. Otherwise, `semzcnt` is incremented by 1, and the process sleeps until one of the following occurs:
 - `semval` becomes 0, at which time the value of `semzcnt` is decremented.
 - The semaphore set is removed, causing the system call to fail with `errno` set to `EIDRM`.
 - The calling process receives a signal that has to be caught; which causes the value of `semzcnt` to be decremented and the system call to fail with `errno` set to `EINTR`.
- If `sem_op` is less than 0, the process must have alter permissions on the semaphore set. If `semval` is greater than or equal to the absolute value of `sem_op`, the absolute value of `sem_op` is subtracted by `semval`. Furthermore, if `SEM_UNDO` is asserted for this operation, the system updates the process undo count for this semaphore. Then the operation goes through. Otherwise, if `IPC_NOWAIT` is asserted in `sem_flg`, the system call fails (undoing all previous actions performed), with `errno` set to `EAGAIN`. Otherwise, `semncnt` is incremented by 1 and the process sleeps until one of the following occurs:
 - `semval` becomes greater than or equal to the absolute value of `sem_op`, at which time the value of `semncnt` is decremented, the absolute value of `sem_op` is subtracted from `semval` and, if `SEM_UNDO` is asserted for this operation, the system updates the process undo count for this semaphore.
 - The semaphore set is removed from the system: the system call fails, with `errno` set to `EIDRM`.
 - The calling process receives a signal that has to be caught; the value of `semncnt` is decremented, and the system call fails with `errno` set to `EINTR`.

In case of success, the `sempid` member of the structure `sem` for each semaphore specified in the array pointed to by `sops` is set to the process ID of the calling process. Furthermore both `sem_otime` and `sem_ctime` are set to the current time.

RETURN VALUE

If successful, the system call returns 0; otherwise, it returns -1, with `errno` indicating the error.

ERRORS

For a failing return, `errno` will be set to one of the following values:

E2BIG	The argument <code>nsops</code> is greater than <code>SEMOPM</code> , the maximum number of operations allowed per system call.
EACCES	The calling process has no access permissions on the semaphore set as required by one of the specified operations.
EAGAIN	An operation could not go through, and <code>IPC_NOWAIT</code> was asserted in its <code>sem_flg</code> .
EFAULT	The address pointed to by <code>sops</code> isn't accessible.

EFBIG	For some operation, the value of <code>sem_num</code> is less than 0 or greater than or equal to the number of semaphores in the set.
EIDRM	The semaphore set was removed.
EINTR	Sleeping on a wait queue, the process received a signal that had to be caught.
EINVAL	The semaphore set doesn't exist, or <code>semi_d</code> is less than 0, or <code>nsops</code> has a non-positive value.
ENOMEM	The <code>sem_flg</code> of some operation asserted <code>SEM_UNDO</code> , and the system does not have enough memory to allocate the undo structure.
ERANGE	For some operation, <code>semop+semvalis</code> is greater than <code>SEMVMX</code> , the implementation-dependent maximum value for <code>semval</code> .

NOTES

The `sem_undo` structures of a process aren't inherited by its child on execution of a `fork(2)` system call. They are instead inherited by the substituting process resulting from the execution of the `exec(2)` system call.

The following are limits on semaphore set resources affecting a `semop` call:

<code>SEMOPM</code>	Maximum number of operations allowed for one <code>semop</code> call; policy dependent.
<code>SEMVMX</code>	Maximum allowable value for <code>semval</code> ; implementation dependent (32767).

The implementation has no intrinsic limits for the `adjust on exit` maximum value (`SEMAEM`), the system-wide maximum number of undo structures (`SEMMNU`), or the per-process maximum number of undo entries system parameters.

BUGS

The system maintains a per-process `sem_undo` structure for each semaphore altered by the process with undo requests. Those structures are free at process exit. One major cause for unhappiness with the undo mechanism is that it does not fit in with the notion of having an atomic set of operations in an array of semaphores. The undo requests for an array and each semaphore therein might have been accumulated over many `semopt` calls. Should the process sleep when exiting, or should all undo operations be applied with the `IPC_NOWAIT` flag in effect? Currently those undo operations that go through immediately are applied, and those that require a wait are ignored silently. Therefore harmless undo usage is guaranteed with private semaphores only.

Linux 0.99.13, 1 November 1993

send, sendto, sendmsg

`send`, `sendto`, `sendmsg`—Sends a message from a socket

SYNOPSIS

```
#include <sys/types.h>
#include <sys/socket.h>
int send(int s, const void *msg, int len, unsigned int flags);
int sendto(int s, const void *msg, int len, unsigned int flags,
           const struct sockaddr *to, int tolen);
int sendmsg(int s, const struct msghdr *msg, unsigned int flags);
```

DESCRIPTION

Warning: This is a BSD man page. As of Linux 0.99.11, `sendmsg` was not implemented.

`send`, `sendto`, and `sendmsg` are used to transmit a message to another socket. `send` may be used only when the socket is in a connected state, whereas `sendto` and `sendmsg` may be used at any time.

The address of the target is given by `to`, with `toLen` specifying its size. The length of the message is given by `len`. If the message is too long to pass atomically through the underlying protocol, the error `EMSGSIZE` is returned, and the message is not transmitted.

No indication of failure to deliver is implicit in a `send`. Locally detected errors are indicated by a return value of `-1`.

If no message space is available at the socket to hold the message to be transmitted, `send` normally blocks, unless the socket has been placed in non-blocking I/O mode. The `select(2)` call may be used to determine when it is possible to send more data.

The `flags` parameter may include one or more of the following:

```
#define MSG_OOB 0x1 /* process out-of-band data */
#define MSG_DONTROUTE 0x4 /* bypass routing, use direct interface */
```

The flag `MSG_OOB` is used to send out-of-band data on sockets that support this notion (for example, `SOCK_STREAM`); the underlying protocol must also support out-of-band data. `MSG_DONTROUTE` is usually used only by diagnostic or routing programs.

See `recv(2)` for a description of the `msghdr` structure.

RETURN VALUES

The call returns the number of characters sent, or `-1` if an error occurred.

ERRORS

<code>EBADF</code>	An invalid descriptor was specified.
<code>ENOTSOCK</code>	The argument <code>s</code> is not a socket.
<code>EFAULT</code>	An invalid user space address was specified for a parameter.
<code>EMSGSIZE</code>	The socket requires that message be sent atomically, and the size of the message to be sent made this impossible.
<code>EWOULDBLOCK</code>	The socket is marked non-blocking, and the requested operation would block.
<code>ENOBUFS</code>	The system was unable to allocate an internal buffer. The operation might succeed when buffers become available.
<code>ENOBUFS</code>	The output queue for a network interface was full. This generally indicates that the interface has stopped sending, but it might be caused by transient congestion.

HISTORY

These function calls appeared in BSD 4.2.

setfsuid

`setfsuid`—Sets group identity used for filesystem checks

SYNOPSIS

```
int setfsuid(uid_t fsuid);
```

DESCRIPTION

`setfsuid` sets the group ID that the Linux kernel uses to check for all accesses to the filesystem. Normally, the value of `fsuid` will shadow the value of the effective group ID. In fact, whenever the effective group ID is changed, `fsuid` will also be changed to the new value of the effective group ID.

An explicit call to `setfsgid` is usually only used by programs such as the Linux NFS server that need to change what group ID is used for file access without a corresponding change in the real and effective group IDs. A change in the normal group IDs for a program such as the NFS server is a security hole that can expose it to unwanted signals from other group IDs.

`setfsgid` will succeed only if the caller is the superuser or if `fsgid` matches either the real group ID, effective group ID, saved group ID, or the current value of `fsgid`.

RETURN VALUE

On success, the previous value of `fsgid` is returned. On error, the current value of `fsgid` is returned.

CONFORMS TO

`setfsgid` is Linux specific.

BUGS

No error messages of any kind are returned to the caller. At the very least, `EPERM` should be returned when the call fails.

setgid

setgid—Sets group identity

SYNOPSIS

```
#include <unistd.h>
int setgid(gid_t gid);
```

DESCRIPTION

setgid sets the effective group ID of the current process. If the caller is the superuser, the real and saved group IDs are also set.

Under Linux, setgid is implemented like SYSV, with SAVED_IDS. This allows a setgid (other than root) program to drop all its group privileges, do some unprivileged work, and then re-engage the original effective group ID in a secure manner.

If the user is root or the program is setgid root, special care must be taken. The setgid function checks the effective gid of the caller and, if it is that of the superuser, all process-related group IDs are set to gid. After this has occurred, it is impossible for the program to regain root privileges.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and errno is set appropriately.

ERRORS

EPERM The user is not the superuser, and gid does not match the effective or saved group ID of the calling process.

CONFORMS TO

System V

setpgid, getpgid, setpgrp, getpgrp

setpgid, getpgid, setpgrp, getpgrp—Sets/gets process group

SYNOPSIS

```
#include <unistd.h>
int setpgid(pid_t pid, pid_t pgid);
pid_t getpgid(pid_t pid);
int setpgrp(void);
pid_t getpgrp(void);
```

DESCRIPTION

setpgid sets the process group ID of the process specified by pid to pgid. If pid is 0, the process ID of the current process is used. If pgid is 0, the process ID of the process specified by pid is used.

getpgid returns the process group ID of the process specified by pid. If pid is 0, the process ID of the current process is used.

In the Linux DLL 4.4.1 library, setpgrp simply calls setpgid(0,0).

getpgrp is equivalent to getpgid(0).

Process groups are used for distribution of signals, and by terminals to arbitrate requests for their input; processes that have the same process group as the terminal are foreground and may read, whereas others will block with a signal if they attempt to read.

These calls are thus used by programs such as `csh(1)` to create process groups in implementing job control. The `TIOCGRP` and `TIOCSGRP` calls described in `termios(4)` are used to get/set the process group of the control terminal.

RETURN VALUE

On success, `setpgid` and `setpgrp` return `0`. On error, `-1` is returned, and `errno` is set appropriately.

`getpgid` returns a process group on success. On error, `-1` is returned, and `errno` is set appropriately.

`getpgrp` always returns the current process group.

ERRORS

<code>EINVAL</code>	<code>pgid</code> is less than <code>0</code> .
<code>EPERM</code>	Various permission violations.
<code>ESRCH</code>	<code>pid</code> does not match any process.

CONFORMS TO

The functions `setpgid` and `getpgrp` conform to POSIX.1. The function `setpgrp` is from BSD 4.2. I have no information on the source of `getpgid`.

Linux 1.2.4, 15 April 1995

setregid, setegid

`setregid`, `setegid`—Sets real and/or effective group ID

SYNOPSIS

```
#include <unistd.h>
int setregid(gid_t rgid, gid_t egid);
int setegid(gid_t egid);
```

DESCRIPTION

`setregid` sets real and effective group IDs of the current process. Unprivileged users may change the real group ID to the effective group ID, and vice versa.

Prior to Linux 1.1.38, the saved ID paradigm, when used with `setregid` or `setegid`, was broken. Starting at 1.1.38, it is also possible to set the effective group ID from the saved user ID.

Only the superuser may make other changes.

Supplying a value of `-1` for either the real or effective group ID forces the system to leave that ID unchanged.

Currently (`libc-4.x.x`), `setegid(egid)` is functionally equivalent to `setregid(-1, egid)`.

If the real group ID is changed or the effective group ID is set to a value not equal to the previous real group ID, the saved group ID will be set to the new effective group ID.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

EPERM

The current process is not the superuser, and changes other than swapping the effective group ID with the real group ID, setting one to the value of the other, or setting the effective group ID to the value of the saved group ID was specified.

HISTORY

The `setregid` function call appeared in BSD 4.2.

CONFORMS TO

BSD 4.3

setreuid, seteuid

setreuid, seteuid—Sets real and / or effective user ID

SYNOPSIS

```
#include <unistd.h>
int setreuid(uid_t ruid, uid_t euid);
int seteuid(uid_t euid);
```

DESCRIPTION

`setreuid` sets real and effective user IDs of the current process. Unprivileged users may change the real user ID to the effective user ID, and vice versa.

Prior to Linux 1.1.37, the saved ID paradigm, when used with `setreuid` or `seteuid`, was broken.

Starting at 1.1.37, it is also possible to set the effective user ID from the saved user ID.

Only the superuser may make other changes.

Supplying a value of `-1` for either the real or effective user ID forces the system to leave that ID unchanged.

Currently (`libc-4.x.x`), `seteuid(euid)` is functionally equivalent to `setreuid(-1, euid)`.

If the real user ID is changed or the effective user ID is set to a value not equal to the previous real user ID, the saved user ID will be set to the new effective user ID.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

EPERM

The current process is not the superuser, and changes other than swapping the effective user ID with the real user ID, setting one to the value of the other, or setting the effective user ID to the value of the saved user ID was specified.

HISTORY

The `setreuid` function call appeared in BSD 4.2.

CONFORMS TO

BSD 4.3

setsid

`setsid`—Creates a session and sets the process group ID

SYNOPSIS

```
#include <unistd.h>
pid_t setsid(void);
```

DESCRIPTION

`setsid()` creates a new session if the calling process is not a process group leader. The calling process is the leader of the new session, the process group leader of the new process group, and has no controlling tty. The process group ID and session ID of the calling process are set to the PID of the calling process. The calling process will be the only process in this new process group and in this new session.

RETURN VALUE

It returns the session ID of the calling process.

ERRORS

On error, `-1` will be returned. The only error that can happen is `EPERM`, which is returned when the process group ID of any process equals the PID of the calling process. Thus, in particular, `setsid` fails if the calling process is already a process group leader.

NOTES

A *process group leader* is a process with process group ID equal to its PID. In order to be sure that `setsid` will succeed, `fork`, `and exit`, and have the child do `setsid()`.

CONFORMS TO

POSIX

setuid

`setuid`—Sets user identity

SYNOPSIS

```
#include <unistd.h>
int setuid(uid_t uid);
```

DESCRIPTION

`setuid` sets the effective user ID of the current process. If the caller is the superuser, the real and saved user IDs are also set.

Under Linux, `setuid` is implemented like `SYSV`, with `SAVED_IDS`. This allows a `setuid` (other than `root`) program to drop all its user privileges, do some unprivileged work, and then re-engage the original effective user ID in a secure manner.

If the user is `root` or the program is `setuid root`, special care must be taken. The `setuid` function checks the effective UID of the caller, and, if it is the superuser, all process-related user IDs are set to `uid`. After this has occurred, it is impossible for the program to regain root privileges.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

`EPERM` The user is not the superuser, and `uid` does not match the effective or saved user ID of the calling process.

setup

`setup`—Sets up devices and filesystems, mount root filesystem

SYNOPSIS

```
#include <unistd.h>
syscall0(int, setup);
int setup(void);
```

DESCRIPTION

`setup` is called once from within `linux/init/main.c`. It calls initialization functions for devices and filesystems configured into the kernel and then mounts the root filesystem.

No user process may call `setup`. Any user process, even a process with superuser permission, will receive `EPERM`.

RETURN VALUE

`setup` always returns `-1` for a user process.

ERRORS

`EPERM` Always, for a user process.

CONFORMS TO

This function is Linux specific.

Linux 1.2.9, 3 May 1996

shmctl

`shmctl`—Shared memory control

SYNOPSIS

```
#include <sys/ipc.h>
#include <sys/shm.h>
int shmctl(int shmid,int cmd, struct shmid_ds *buf);
```

DESCRIPTION

shmctl() allows the user to receive information on a shared memory segment, set the owner, group, and permissions of a shared memory segment, or destroy a segment. The information about the segment identified by shmid is returned in a shmid_ds structure:

```
struct shmid_ds {
    struct ipc_perm shm_perm; /* operation perms */
    int shm_segsz; /* size of segment (bytes) */
    time_t shm_atime; /* last attach time */
    time_t shm_dtime; /* last detach time */
    time_t shm_ctime; /* last change time */
    unsigned short shm_cpid; /* pid of creator */
    unsigned short shm_lpid; /* pid of last operator */
    short shm_nattch; /* no. of current attaches */
    /* the following are private */
    unsigned short shm_npages; /* size of segment (pages) */
    unsigned long *shm_pages;
    struct shm_desc *attaches; /* descriptors for attaches */
};
```

The fields in the member shm_perm can be set:

```
struct ipc_perm
{
    key_t key;
    ushort uid; /*owner euid and egid */
    ushort gid;
    ushort cuid; /* creator euid and egid */
    ushort cgid;
    ushort mode; /* lower 9 bits of access modes */
    ushort seq; /* sequence number */
};
```

The following cmds are available:

IPC_STAT	Used to copy the information about the shared memory segment into the buffer, buf. The user must have read access to the shared memory segment.
IPC_SET	Used to apply the changes the user has made to the uid, gid, or mode members of the shm_perms field. Only the lowest 9 bits of mode are used. The shm_ctime member is also updated. The user must be the owner, the creator, or the superuser.
IPC_RMID	Used to mark the segment as destroyed. It will actually be destroyed after the last detach. (That is, when the shm_nattch member of the associated structure shmid_ds is zero.)The user must be the owner, the creator, or the superuser.

The user must ensure that a segment is eventually destroyed; otherwise the pages that were faulted in will remain in memory or swap.

In addition, the superuser can prevent or allow swapping of a shared memory segment with the following cmds: (Linux only)

SHM_LOCK	Prevents swapping of a shared memory segment. The user must fault in any pages that are required to be present after locking is enabled.
SHM_UNLOCK	Allows the shared memory segment to be swapped out.

The IPC_INFO, SHM_STAT, and SHM_INFO control calls are used by the ipcs(1) program to provide information on allocated resources. In the future, these may be modified as needed or moved to a proc filesystem interface.

SYSTEM CALLS

<code>fork()</code>	After a <code>fork()</code> , the child inherits the attached shared memory segments.
<code>exec()</code>	After an <code>exec()</code> , all attached shared memory segments are detached (not destroyed).
<code>exit()</code>	On <code>exit()</code> , all attached shared memory segments are detached (not destroyed).

RETURN VALUE

0 is returned on success; -1 on error.

ERRORS

On error, `errno` will be set to one of the following:

<code>EACCESS</code>	Returned if <code>IPC_STAT</code> is requested and <code>shm_perm.modes</code> does not allow read access for <code>msqid</code> .
<code>EFAULT</code>	The argument <code>cmd</code> has the value <code>IPC_SET</code> or <code>IPC_STAT</code> , but the address pointed to by <code>buf</code> isn't accessible.
<code>EINVAL</code>	Returned if <code>shmid</code> is not a valid identifier, or <code>cmd</code> is not a valid command.
<code>EIDRM</code>	Returned if <code>shmid</code> points to a removed identifier.
<code>EPERM</code>	Returned if <code>IPC_SET</code> or <code>IPC_RMID</code> is attempted, if the user is not the creator, the owner, or the superuser, and if the user does not have permission granted to his group or to the world.

SEE ALSO

`shmget(2)`, `shmop(2)`

Linux 0.99.11, 28 November 1993

shmget

`shmget`—Allocates a shared memory segment

SYNOPSIS

```
#include <sys/ipc.h>
#include <sys/shm.h>
int shmget(key_t key, int size, int shmflg);
```

DESCRIPTION

`shmget()` returns the identifier of the shared memory segment associated with the value of the argument `key`. A new shared memory segment, with its size equal to the rounding up of `size` to a multiple of `PAGE_SIZE`, is created if `key` has the value `IPC_PRIVATE` or if `key` isn't `IPC_PRIVATE`, if no shared memory segment is associated to `key`, and if `IPC_CREAT` is asserted in `shmflg` (that is, `shmflg & IPC_CREAT` isn't 0). The presence in `shmflg` is composed of

<code>IPC_CREAT</code>	Creates a new segment. If this flag is not used, <code>shmget()</code> will find the segment associated with <code>key</code> , check to see if the user has permission to receive the <code>shmid</code> associated with the segment, and ensure the segment is not marked for destruction.
<code>IPC_EXCL</code>	Used with <code>IPC_CREAT</code> to ensure failure if the segment exists.
<code>mode_flags</code>	(lowest 9 bits) Specifies the permissions granted to the owner, group, and world. Presently, the execute permissions are not used by the system.

If a new segment is created, the access permissions from `shmflg` are copied into the `shm_perm` member of the `shmid_ds` structure that defines the segment. Following is the `shmid_ds` structure:

```
struct shmid_ds {
    struct ipc_perm shm_perm; /* operation perms */
    int shm_segsz; /* size of segment (bytes) */
```

```

time_t shm_atime; /* last attach time */
time_t shm_dtime; /* last detach time */
time_t shm_ctime; /* last change time */
unsigned short shm_cpid; /* pid of creator */
unsigned short shm_lpid; /* pid of last operator */
short shm_nattch; /* no. of current attaches */
};

struct ipc_perm
{
    key_t key;
    ushort uid; /* owner euid and egid */
    ushort gid;
    ushort cuid; /* creator euid and egid */
    ushort cgid;
    ushort mode; /* lower 9 bits of shmflg */
    ushort seq; /* sequence number */
};

```

Furthermore, while creating, the system call initializes the system shared memory segment data structure `shm_id_ds` as follows:

- `shm_perm.cuid` and `shm_perm.uid` are set to the effective user ID of the calling process.
- `shm_perm.cgid` and `shm_perm.gid` are set to the effective group ID of the calling process.
- The lowest-order 9 bits of `shm_perm.mode` are set to the lowest-order 9 bits of `shmflg`.
- `shm_segsz` is set to the value of `size`.
- `shm_lpid`, `shm_nattch`, `shm_atime`, and `shm_dtime` are set to 0.
- `shm_ctime` is set to the current time.

If the shared memory segment already exists, the access permissions are verified, and a check is made to see if it is marked for destruction.

SYSTEM CALLS

<code>fork()</code>	After a <code>fork()</code> , the child inherits the attached shared memory segments.
<code>exec()</code>	After an <code>exec()</code> , all attached shared memory segments are detached (not destroyed).
<code>exit()</code>	On <code>exit()</code> , all attached shared memory segments are detached (not destroyed).

RETURN VALUE

A valid segment identifier, `shm_id`, is returned on success, -1 on error.

ERRORS

On failure, `errno` is set to one of the following:

<code>EINVAL</code>	Returned if <code>SHMMIN</code> is greater than <code>size</code> , if <code>size</code> is greater than <code>SHMMAX</code> , or if <code>size</code> is greater than the size of the segment.
<code>EEXIST</code>	Returned if <code>IPC_CREAT</code> <code>IPC_EXCL</code> was specified and the segment exists.
<code>EIDRM</code>	Returned if the segment is marked as destroyed or was removed.
<code>ENOSPC</code>	Returned if all possible shared memory IDs have been taken (<code>SHMMNI</code>) or if allocating a segment of the requested size would cause the system to exceed the system-wide limit on shared memory (<code>SHMALL</code>).
<code>ENOENT</code>	Returned if no segment exists for the given <code>key</code> , and <code>IPC_CREAT</code> was not specified.
<code>EACCES</code>	Returned if the user does not have permission to access the shared memory segment.
<code>ENOMEM</code>	Returned if no memory could be allocated for segment overhead.

NOTES

`IPC_PRIVATE` isn't a flag field but a `key_t` type. If this special value is used for `key`, the system call ignores everything but the lowest order 9 bits of `shmflg` and creates a new shared memory segment (on success).

The following are limits on shared memory segment resources affecting a `shmget` call:

<code>SHMALL</code>	System-wide maximum of shared memory pages; policy dependent.
<code>SHMMAX</code>	Maximum size, in bytes, for a shared memory segment; implementation dependent (currently 4MB).
<code>SHMMIN</code>	Minimum size, in bytes, for a shared memory segment; implementation dependent (currently 1 byte, although <code>PAGE_SIZE</code> is the effective minimum size).
<code>SHMMNI</code>	System-wide maximum number of shared memory segments; implementation dependent (currently 4096).

The implementation has no specific limits for the per-process maximum number of shared memory segments (`SHMSEG`).

BUGS

Use of `IPC_PRIVATE` does not inhibit other processes' access to the allocated shared memory segment.

As for the files, there is currently no intrinsic way for a process to ensure exclusive access to a shared memory segment. Asserting both `IPC_CREAT` and `IPC_EXCL` in `shmflg` only ensures (on success) that a new shared memory segment will be created; it doesn't imply exclusive access to the segment.

Linux 0.99.11, 28 November 1993

shmop

shmop—Shared memory operations

SYNOPSIS

```
#include <sys/types.h>
#include <sys/ipc.h>
#include <sys/shm.h>
char *shmat ( int shmid, char *shmaddr, int shmflg );
int shmdt ( char *shmaddr );
```

DESCRIPTION

The function `shmat` attaches the shared memory segment identified by `shmid` to the data segment of the calling process. The attaching address is specified by `shmaddr` with one of the following criteria:

- If `shmaddr` is 0, the system tries to find an unmapped region in the range 1–1.5GB, starting from the upper value and coming down from there.
- If `shmaddr` isn't 0 and `SHM_RND` is asserted in `shmflg`, the attach occurs at the address equal to the rounding down of `shmaddr` to a multiple of `SHMLBA`. Otherwise, `shmaddr` must be a page-aligned address at which the attach occurs.

If `SHM_RDONLY` is asserted in `shmflg`, the segment is attached for reading, and the process must have read access permissions to the segment. Otherwise the segment is attached for read and write, and the process must have read and write access permissions to the segment. There is no notion of a write-only shared memory segment.

The `brk` value of the calling process is not altered by the attach. The segment will automatically be detached at process exit. The same segment may be attached as a read and as a read-write segment, more than once, in the process's address space.

On a successful `shmat` call, the system updates the members of the structure `shmid_ds` associated to the shared memory segment as follows:

- `shm_atime` is set to the current time.
- `shm_lpid` is set to the process ID of the calling process.
- `shm_nattch` is incremented by 1.

Note that the attachment will also succeed if the shared memory segment is marked to be deleted.

The function `shmdt` detaches from the calling process's data segment the shared memory segment located at the address specified by `shmaddr`. The detaching shared memory segment must be one among the currently attached ones (to the process's address space) with `shmaddr` equal to the value returned by its attaching `shmat` call.

On a successful `shmdt` call, the system updates the members of the structure `shmid_ds` associated to the shared memory segment as follows:

- `shm_dtime` is set to the current time.
- `shm_lpid` is set to the process ID of the calling process.
- `shm_nattch` is decremented by 1. If it becomes 0 and the segment is marked for deletion, the segment is deleted.

The occupied region in the user space of the calling process is unmapped.

SYSTEM CALLS

<code>fork()</code>	After a <code>fork()</code> , the child inherits the attached shared memory segments.
<code>exec()</code>	After an <code>exec()</code> , all attached shared memory segments are detached (not destroyed).
<code>exit()</code>	On <code>exit()</code> , all attached shared memory segments are detached (not destroyed).

RETURN VALUE

On a failure, both functions return `-1` with `errno` indicating the error; otherwise, `shmat` returns the address of the attached shared memory segment, and `shmdt` returns `0`.

ERRORS

When `shmat` fails, at return `errno` will be set to one of the following values:

<code>EACCES</code>	The calling process has no access permissions for the requested attach type.
<code>EINVAL</code>	Invalid <code>shmid</code> value, unaligned (that is, not page-aligned and <code>SHM_RND</code> was not specified) or invalid <code>shmaddr</code> value, or failing attach at <code>brk</code> .
<code>ENOMEM</code>	Could not allocate memory for the descriptor or for the page tables.

The function `shmdt` can fail only if there is no shared memory segment attached at `shmaddr`; in such a case, `errno` will be set to `EINVAL` at return.

NOTES

On executing a `fork(2)` system call, the child inherits all the attached shared memory segments.

The shared memory segments attached to a process executing an `exec(2)` system call will not be attached to the resulting process.

The following is a system parameter affecting a `shmat` system call:

<code>SHMLBA</code>	Segments low-boundary address multiple. Must be page aligned. For the current implementation, the <code>SHMLBA</code> value is <code>PAGE_SIZE</code> .
---------------------	---

The implementation has no intrinsic limit to the per-process maximum number of shared memory segments (`SHMSEG`)

shutdown

shutdown—Shuts down part of a full-duplex connection

SYNOPSIS

```
#include <sys/socket.h>
int shutdown(int s,int how);
```

DESCRIPTION

The `shutdown` call causes all or part of a full-duplex connection on the socket associated with `s` to be shut down. If `how` is `0`, further receives will be disallowed. If `how` is `1`, further sends will be disallowed. If `how` is `2`, further sends and receives will be disallowed.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

EBAADF	<code>s</code> is not a valid descriptor.
ENOTSOCK	<code>s</code> is a file, not a socket.
ENOTCONN	The specified socket is not connected.

HISTORY

The `shutdown` function call appeared in BSD 4.2.

SEE ALSO

sigaction, sigprocmask, sigpending, sigsuspend

sigaction, sigprocmask, sigpending, sigsuspend—POSIX signal-handling functions.

SYNOPSIS

```
#include <signal.h>
int sigaction(int signum, const struct sigaction *act, struct sigaction *oldact);
int sigprocmask(int how, const sigset_t *set, sigset_t *oldset);
int sigpending(sigset_t *set);
int sigsuspend(const sigset_t *mask);
```

DESCRIPTION

The `sigaction` system call is used to change the action taken by a process on receipt of a specific signal.

`signum` specifies the signal and can be any valid signal except `SIGKILL` and `SIGSTOP`.

If `act` is non-null, the new action for signal `signum` is installed from `act`. If `oldact` is non-null, the previous action is saved in `oldact`.

The `sigaction` structure is defined as

```
struct sigaction {
    void (*sa_handler)(int);
    sigset_t sa_mask;
    int sa_flags;
```

```
void (*sa_restorer)(void);
}
```

`sa_handler` specifies the action to be associated with `si_gnum` and can be `SIG_DFL` for the default action, `SIG_IGN` to ignore this signal, or a pointer to a signal-handling function.

`sa_mask` gives a mask of signals that should be blocked during execution of the signal handler. In addition, the signal that triggered the handler will be blocked unless the `SA_NODEFER` or `SA_NOMASK` flag is used.

`sa_flags` specifies a set of flags that modify the behavior of the signal-handling process. It is formed by the bitwise OR of zero or more of the following:

<code>SA_NOCLDSTOP</code>	If <code>si_gnum</code> is <code>SIGCHLD</code> , do not receive notification when child processes stop (that is, when child processes receive one of <code>SIGSTOP</code> , <code>SIGTSTP</code> , <code>SIGTTIN</code> , or <code>SIGTTOU</code>).
<code>SA_ONESHOT</code> or <code>SA_RESETHAND</code>	Restores the signal action to the default state once the signal handler has been called. (This is the default behavior of the <code>signal(2)</code> system call.)
<code>SA_RESTART</code>	Provides behavior compatible with BSD signal semantics by making certain system calls restartable across signals.
<code>SA_NOMASK</code> or <code>SA_NODEFER</code>	Does not prevent the signal from being received from within its own signal handler.

The `sa_restorer` element is obsolete and should not be used.

The `sigprocmask` call is used to change the list of currently blocked signals. The behavior of the call is dependent on the value of `how`, as follows:

<code>SIG_BLOCK</code>	The set of blocked signals is the union of the current set and the <code>set</code> argument.
<code>SIG_UNBLOCK</code>	The signals in <code>set</code> are removed from the current set of blocked signals. It is legal to attempt to unblock a signal that is not blocked.
<code>SIG_SETMASK</code>	The set of blocked signals is set to the argument <code>set</code> .

If `ol_dset` is non-null, the previous value of the signal mask is stored in `ol_dset`.

The `sigpending` call allows the examination of pending signals (those that have been raised while blocked). The signal mask of pending signals is stored in `set`.

The `sigsuspend` call temporarily replaces the signal mask for the process with that given by `mask` and then suspends the process until a signal is received.

RETURN VALUES

`sigaction`, `sigprocmask`, `sigpending`, and `sigsuspend` return 0 on success and -1 on error.

ERRORS

<code>EINVAL</code>	An invalid signal was specified. This will also be generated if an attempt is made to change the action for <code>SIGKILL</code> or <code>SIGSTOP</code> , which cannot be caught.
<code>EFAULT</code>	<code>act</code> , <code>ol_dact</code> , <code>set</code> , or <code>ol_dset</code> points to memory that is not a valid part of the process address space.
<code>EINTR</code>	System call was interrupted.

NOTES

It is not possible to block `SIGKILL` or `SIGSTOP` with the `sigprocmask` call. Attempts to do so will be silently ignored.

Setting `SIGCHLD` to `SIG_IGN` provides automatic reaping of child processes.

The POSIX spec only defines `SA_NOCLDSTOP`. Use of other `sa` flags is non-portable.

The `SA_RESETHAND` flag is compatible with the SVR4 flag of the same name.

The `SA_NODEFER` flag is compatible with the SVR4 flag of the same name under kernels 1.3.9 and newer. On older kernels, the Linux implementation will allow the receipt of any signal, not just the one you are installing (effectively overriding any `sa_mask` settings).

The `SA_RESETHAND` and `SA_NODEFER` names for SVR4 compatibility are present only in library versions 3.0.9 and greater.

`sigaction` can be called with a null second argument to query the current signal handler. It can also be used to check whether a given signal is valid for the current machine by calling it with null second and third arguments.

See `sigsetops(3)` for details on manipulating signal sets.

signal

signal—ANSI C signal handling

SYNOPSIS

```
#include <signal.h>
void (*signal(int signum, void (*handler)(int)))(int);
```

DESCRIPTION

The `signal` system call installs a new signal handler for the signal with number `signum`. The signal handler is set to `handler`, which can be a user-specified function or one of the following:

<code>SIG_IGN</code>	Ignores the signal.
<code>SIG_DFL</code>	Resets the signal to its default behavior.

The integer argument that is handed over to the signal-handling routine is the signal number. This makes it possible to use one signal handler for several signals.

RETURN VALUE

`signal` returns the previous value of the signal handler, or `SIG_ERR` on error.

NOTES

Signal handlers cannot be set for `SIGKILL` or `SIGSTOP`.

Unlike on BSD systems, signals under Linux are reset to their default behavior when raised. However, if you include `<bsd/signal.h>` instead of `<signal.h>`, `signal` is redefined as `_bsd_signal`, and `signal` has the BSD semantics. Both versions of `signal` are library routines built on top of `sigaction(2)`.

If you're confused by the prototype at the top of this man page, it may help to see it separated out like this:

```
typedef void (*sighandler_t)(int);
sighandler_t signal(int signum, sighandler_t handler);
```

According to POSIX, the behavior of a process is undefined after it ignores a `SIGFPE`, `SIGILL`, or `SIGSEGV` signal that was not generated by the `kill()` or `raise()` function. Integer division by 0 has undefined result. On some architectures it will generate a `SIGFPE` signal. Ignoring this signal might lead to an endless loop.

CONFORMS TO

ANSI C

sigblock, siggetmask, sigsetmask, sigmask

`sigblock`, `siggetmask`, `sigsetmask`, `sigmask`—Manipulate the signal mask

SYNOPSIS

```
#include <signal.h>
int sigblock(int mask);
int siggetmask(void);
int sigsetmask(int mask);
int sigmask(int snum);
```

DESCRIPTION

This interface is made obsolete by `sigprocmask(2)`.

The `sigblock` system call adds the signals specified in `mask` to the set of signals currently being blocked from delivery.

The `sigsetmask` system call replaces the set of blocked signals totally with a new set specified in `mask`. Signals are blocked if the corresponding bit in `mask` is a 1.

The current set of blocked signals can be obtained using `siggetmask`.

The `sigmask` macro is provided to construct the mask for a given `snum`.

RETURN VALUES

`siggetmask` returns the current set of masked signals.

`sigsetmask` and `sigblock` return the previous set of masked signals.

NOTES

Prototypes for these functions are only available if `__USE_BSD` is defined before `<signal.h>` is included.

It is not possible to block `SIGKILL` or `SIGSTOP`—this restriction is silently imposed by the system.

HISTORY

These function calls appeared in BSD 4.3 and are deprecated.

SEE ALSO

`kill(2)`, `sigprocmask(2)`, `signal(7)`

Linux 1.3, 31 August 1995

sigpause

`sigpause`—Atomically releases blocked signals and waits for interrupt

SYNOPSIS

```
#include <signal.h>
int sigpause(int sigmask);
```

DESCRIPTION

This interface is made obsolete by `sigsuspend(2)`.

`sigpause` assigns `sigmask` to the set of masked signals and then waits for a signal to arrive; on return, the set of masked signals is restored.

`sigmask` is usually `0` to indicate that no signals are to be blocked. `sigpause` always terminates by being interrupted, returning `-1` with `errno` set to `EINTR`.

HISTORY

The `sigpause` function call appeared in BSD 4.3 and is deprecated.

SEE ALSO

`sigsuspend(2)`, `kill(2)`, `sigaction(2)`, `sigprocmask(2)`, `sigblock(2)`, `sigvec(2)`

Linux 1.3, 24 July 1993

sigreturn

`sigreturn`—Returns from the signal handler and cleans up the stack frame

SYNOPSIS

```
int sigreturn(unsigned long __unused);
```

DESCRIPTION

When the Linux kernel creates the stack frame for a signal handler, a call to `sigreturn` is inserted into the stack frame so that the signal handler will call `sigreturn` upon return. This inserted call to `sigreturn` cleans up the stack so that the process can restart from where it was interrupted by the signal.

RETURN VALUE

`sigreturn` never returns.

WARNING

The `sigreturn` call is used by the kernel to implement signal handlers. It should never be called directly. Better yet, the specific use of the unused argument varies depending on the architecture.

CONFORMS TO

`sigreturn` is specific to Linux.

FILES

```
/usr/src/linux/arch/i386/kernel/signal.c
/usr/src/linux/arch/alpha/kernel/entry.S

sigvec

sigvec—BSD software signal facilities

SYNOPSIS

```
#include <bsd/signal.h>
int sigvec(int sig, struct sigvec *vec, struct sigvec *ovec);
```

DESCRIPTION

This interface is made obsolete by `sigaction(2)`.

Under Linux, `sigvec` is `#defined` to `sigaction`, and provides at best a rough approximation of the BSD `sigvec` interface.

socket

socket—Creates an endpoint for communication

SYNOPSIS

```
#include <sys/types.h>
#include <sys/socket.h>
int socket(int domain, int type, int protocol);
```

DESCRIPTION

`socket` creates an endpoint for communication and returns a descriptor.

The `domain` parameter specifies a communications domain within which communication will take place; this selects the protocol family that should be used. These families are defined in the include file `sys/socket.h`. The currently understood formats are

<code>AF_UNIX</code>	UNIX internal protocols
<code>AF_INET</code>	ARPA Internet protocols
<code>AF_ISO</code>	ISO protocols
<code>AF_NS</code>	Xerox Network Systems protocols
<code>AF_IMPLINK</code>	IMP host at IMP link layer

The `socket` has the indicated type, which specifies the semantics of communication. The currently defined types are

```
SOCK_STREAM
SOCK_DGRAM
SOCK_RAW
SOCK_SEQPACKET
SOCK_RDM
```

A `SOCK_STREAM` type provides sequenced, reliable, two-way connection-based byte streams. An out-of-band data transmission mechanism may be supported. A `SOCK_DGRAM` socket supports datagrams (connectionless, unreliable messages of a fixed, typically small, maximum length). A `SOCK_SEQPACKET` socket may provide a sequenced, reliable, two-way connection-based data transmission path for datagrams of fixed maximum length; a consumer might be required to read an entire packet with each read system call. This facility is protocol specific, and presently is implemented only for `PF_NS`. `SOCK_RAW` sockets provide

access to internal network protocols and interfaces. The types `SOCK_RAW`, which is available only to the superuser, and `SOCK_RDM`, which is planned but not yet implemented, are not described here.

The `protocol` specifies a particular protocol to be used with the socket. Normally only a single protocol exists to support a particular socket type within a given protocol family. However, it is possible that many protocols may exist, in which case a particular protocol must be specified in this manner. The protocol number to use is particular to the communication domain in which communication is to take place; see `protocols(5)`.

Sockets of type `SOCK_STREAM` are full-duplex byte streams, similar to pipes. A stream socket must be in a connected state before any data can be sent or received on it. A connection to another socket is created with a `connect(2)` call. Once connected, data may be transferred using `read(2)` and `write(2)` calls or some variant of the `send(2)` and `recv(2)` calls. When a session has been completed, a `close(2)` may be performed. Out-of-band data can also be transmitted as described in `send(2)` and received as described in `recv(2)`.

The communications protocols used to implement a `SOCK_STREAM` ensure that data is not lost or duplicated. If a piece of data for which the peer protocol has buffer space cannot be successfully transmitted within a reasonable length of time, the connection is considered broken, and calls will indicate an error with `-1` returns and with `ETIMEDOUT` as the specific code in the global variable `errno`. The protocols optionally keep sockets warm by forcing transmissions roughly every minute in the absence of other activity. An error is then indicated if no response can be elicited on an otherwise idle connection for a extended period (for example, 5 minutes). A `SIGPIPE` signal is raised if a process sends on a broken stream; this causes naive processes, which do not handle the signal, to exit.

`SOCK_SEQPACKET` sockets employ the same system calls as `SOCK_STREAM` sockets. The only difference is that `read(2)` calls will return only the amount of data requested, and any that is remaining in the arriving packet will be discarded.

`SOCK_DGRAM` and `SOCK_RAW` sockets allow the sending of datagrams to correspondents named in `send(2)` calls. Datagrams are generally received with `recvfrom(2)`, which returns the next datagram with its return address.

An `fcntl(2)` call can be used to specify a process group to receive a `SIGURG` signal when the out-of-band data arrives. It can also enable non-blocking I/O and asynchronous notification of I/O events via `SIGIO`.

The operation of sockets is controlled by socket-level options. These options are defined in the file `sys/socket.h`. `setsockopt(2)` and `getsockopt(2)` are used to set and get options, respectively.

RETURN VALUES

A `-1` is returned if an error occurs; otherwise, the return value is a descriptor referencing the socket.

ERRORS

<code>EPROTONOSUPPORT</code>	The protocol type or the specified protocol is not supported within this domain.
<code>EMFILE</code>	The per-process descriptor table is full.
<code>ENFILE</code>	The system file table is full.
<code>EACCESS</code>	Permission to create a socket of the specified type and/or protocol is denied.
<code>ENOBUFS</code>	Insufficient buffer space is available. The socket cannot be created until sufficient resources are freed.

HISTORY

The `socket` function call appeared in BSD 4.2.

socketcall

socketcall—Socket system calls

SYNOPSIS

```
int socketcall(int call, unsigned long *args);
```

DESCRIPTION

`socketcall` is a common kernel entry point for the socket system calls. `call` determines which socket function to invoke. `args` points to a block containing the actual arguments, which are passed through to the appropriate call.

User programs should call the appropriate functions by their usual names. Only standard library implementors and kernel hackers need to know about `socketcall`.

Linux 1.2.4, 15 April 1995

socketpair

socketpair—Creates a pair of connected sockets

SYNOPSIS

```
#include <sys/types.h>
#include <sys/socket.h>
int socketpair(int d, int type, int protocol, int sv[2]);
```

DESCRIPTION

The call creates an unnamed pair of connected sockets in the specified domain `d`, of the specified `type`, and using the optionally specified `protocol`. The descriptors used in referencing the new sockets are returned in `sv[0]` and `sv[1]`. The two sockets are indistinguishable.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

EMFILE	Too many descriptors are in use by this process.
EAFNOSUPPORT	The specified address family is not supported on this machine.
EPROTONOSUPPORT	The specified protocol is not supported on this machine.
EOPNOSUPPORT	The specified protocol does not support creation of socket pairs.
EFAULT	The address <code>sv</code> does not specify a valid part of the process's address space.

HISTORY

The `socketpair` function call appeared in BSD 4.2.

BUGS

This call is currently implemented only for the UNIX domain.

stat, fstat, lstat

stat, fstat, lstat—Get file status

SYNOPSIS

```
#include <sys/stat.h>
#include <unistd.h>
int stat(const char *file_name, struct stat *buf);
int fstat(int fildes, struct stat *buf);
int lstat(const char *file_name, struct stat *buf);
```

DESCRIPTION

These functions return information about the specified file. You do not need any access rights to the file to get this information, but you need search rights to all directories named in the path leading to the file.

stat stats the file pointed to by `file_name` and fills in `buf`.

lstat is identical to stat, except that the link itself is stated, not the file that is obtained by tracing the links.

fstat is identical to stat, except that the open file pointed to by `fildes` (as returned by `open(2)`) is stated in place of `file_name`.

They all return a stat structure, which is declared as follows:

```
struct stat
{
    dev_t          st_dev;          /* device */
    ino_t          st_ino;         /* inode */
    umode_t       st_mode;        /* protection */
    nlink_t       st_nlink;       /* number of hard links */
    uid_t         st_uid;         /* user ID of owner */
    gid_t         st_gid;         /* group ID of owner */
    dev_t         st_rdev;        /* device type (if inode device) */
    off_t         st_size;        /* total size, in bytes */
    unsigned long st_blksize;     /* blocksize for filesystem I/O */
    unsigned long st_blocks;     /* number of blocks allocated */
    time_t        st_atime;       /* time of last access */
    time_t        st_mtime;       /* time of last modification */
    time_t        st_ctime;       /* time of last change */
};
```

Note that `st_blocks` may not always be in terms of blocks of size `st_blksize`, and that `st_blksize` may instead provide a notion of the “preferred” block size for efficient filesystem I/O.

Not all the Linux filesystems implement all the time fields. Traditionally, `st_atime` is changed by `mknod(2)`, `utime(2)`, `read(2)`, `write(2)`, and `truncate(2)`.

Traditionally, `st_mtime` is changed by `mknod(2)`, `utime(2)`, and `write(2)`. `st_mtime` is not changed for changes in owner, group, hard link count, or mode.

Traditionally, `st_ctime` is changed by writing or by setting inode information (that is, owner, group, link count, mode, and so on).

The following macros are defined to check the file type:

<code>S_ISLNK(m)</code>	Is it a symbolic link?
<code>S_ISREG(m)</code>	Is it a regular file?
<code>S_ISDIR(m)</code>	Is it a directory?
<code>S_ISCHR(m)</code>	Is it a character device?
<code>S_ISBLK(m)</code>	Is it a block device?
<code>S_ISFIFO(m)</code>	Is it fifo?
<code>S_ISSOCK(m)</code>	Is it a socket?

The following flags are defined for the `st_mode` field:

<code>S_IFMT</code>	00170000 Bitmask for the file type bitfields
<code>S_IFSOCK</code>	0140000 Socket
<code>S_IFLNK</code>	0120000 Symbolic link
<code>S_IFREG</code>	0100000 Regular file
<code>S_IFBLK</code>	0060000 Block device
<code>S_IFDIR</code>	0040000 Directory
<code>S_IFCHR</code>	0020000 Character device
<code>S_IFIFO</code>	0010000 Fifo
<code>S_ISUID</code>	0004000 Set UID bit
<code>S_ISGID</code>	0002000 Set GID bit
<code>S_ISVTX</code>	0001000 Sticky bit
<code>S_IRWXU</code>	00700 User (file owner) has read, write, and execute permission
<code>S_IRUSR (S_IREAD)</code>	00400 User has read permission
<code>S_IWUSR (S_IWRITE)</code>	00200 User has write permission
<code>S_IXUSR (S_IEXEC)</code>	00100 User has execute permission
<code>S_IRWXG</code>	00070 Group has read, write, and execute permission
<code>S_IRGRP</code>	00040 Group has read permission
<code>S_IWGRP</code>	00020 Group has write permission
<code>S_IXGRP</code>	00010 Group has execute permission
<code>S_IRWXO</code>	00007 others have read, write, and execute permission
<code>S_IROTH</code>	00004 Others have read permission
<code>S_IWOTH</code>	00002 Others have write permission
<code>S_IXOTH</code>	00001 Others have execute permission

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

<code>EBADF</code>	filedes is bad.
<code>ENOENT</code>	File does not exist.

CONFORMS TO

SVID (not `lstat()`), AT&T (not `lstat()`), POSIX (not `lstat()`), X/OPEN (not `lstat()`), BSD 4.3

`chmod(2)`, `chown(2)`, `readlink(2)`, `utime(2)`

statfs, fstatfs

statfs, fstatfs—Get filesystem statistics

SYNOPSIS

```
#include <sys/vfs.h>
int statfs(const char *path, struct statfs *buf);
int fstatfs(int fd, struct statfs *buf);
```

DESCRIPTION

statfs returns information about a mounted filesystem. *path* is the pathname of any file within the mounted filesystem. *buf* is a pointer to a **statfs** structure defined as follows:

```
struct statfs {
    long    f_type;          /* type of filesystem (see below) */
    long    f_bsize;        /* optimal transfer block size */
    long    f_blocks;       /* total data blocks in filesystem */
    long    f_bfree;        /* free blocks in fs */
    long    f_bavail;       /* free blocks avail to non-superuser */
    long    f_files;        /* total file nodes in filesystem */
    long    f_ffree;        /* free file nodes in fs */
    fsid_t  f_fsid;         /* filesystem id */
    long    f_namelen;      /* maximum length of filenames */
    long    f_spare[6];     /* spare for later */
};
```

Filesystem types:

```
linux/ext2_fs.h:  EXT2_OLD_SUPER_MAGIC  0xEF51
linux/ext2_fs.h:  EXT2_SUPER_MAGIC      0xEF53
linux/ext_fs.h:   EXT_SUPER_MAGIC       0x137D
linux/iso_fs.h:   ISOFS_SUPER_MAGIC     0x9660
linux/minix_fs.h: MINIX_SUPER_MAGIC     0x137F /* orig. minix */
linux/minix_fs.h: MINIX_SUPER_MAGIC2    0x138F /* 30 char minix */
linux/minix_fs.h: NEW_MINIX_SUPER_MAGIC 0x2468 /* minix V2 */
linux/msdos_fs.h: MSDOS_SUPER_MAGIC     0x4d44
linux/nfs_fs.h:   NFS_SUPER_MAGIC       0x6969
linux/proc_fs.h:  PROC_SUPER_MAGIC     0x9fa0
linux/xia_fs.h:   XIAFS_SUPER_MAGIC     0x012FD16D
```

Fields that are undefined for a particular filesystem are set to -1. **fstatfs** returns the same information about an open file referenced by descriptor *fd*.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and *errno* is set appropriately.

ERRORS

For statfs:

ENOTDIR	A component of the path prefix of <i>path</i> is not a directory.
EINVAL	<i>path</i> contains a character with the high-order bit set.
ENAMETOOLONG	The length of a component of <i>path</i> exceeds 255 characters, or the length of <i>path</i> exceeds 1,023 characters.
ENOENT	The file referred to by <i>path</i> does not exist.
EACCESS	Search permission is denied for a component of the path prefix of <i>path</i> .
ELOOP	Too many symbolic links were encountered in translating <i>path</i> .

EFAULT	<code>buf</code> or <code>path</code> points to an invalid address.
EIO	An I/O error occurred while reading from or writing to the filesystem.
For <code>fstatfs</code>:	
EBAADF	<code>fd</code> is not a valid open file descriptor.
EFAULT	<code>buf</code> points to an invalid address.
EIO	An I/O error occurred while reading from or writing to the filesystem.

stime

`stime`—Set time

SYNOPSIS

```
#include <time.h>
int stime(time_t *t);
```

DESCRIPTION

`stime` sets the system's idea of the time and date. `time`, pointed to by `t`, is measured in seconds from 00:00:00 GMT January 1, 1970. `stime()` may only be executed by the superuser.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

EPERM The caller is not the superuser.

CONFORMS TO

SVID, AT&T, X/OPEN

SEE ALSO

`date(1)`

Linux 0.99.11, 24 July 1993

swapon, swapoff

`swapon`, `swapoff`—Start/stop swapping to file/device

SYNOPSIS

```
#include <unistd.h>
#include <linux/swap.h>
int swapon(const char *path, int swapflags);
int swapoff(const char *path);
```

DESCRIPTION

`swapon` sets the swap area to the file or block device specified by `path`. `swapoff` stops swapping to the file or block device specified by `path`.

`swapon` takes a `swapflags` argument. If `swapflags` has the `SWAP_FLAG_PREFER` bit turned on, the new swap area will have a higher priority than default. The priority is encoded as $(prio \ll SWAP_FLAG_PRIO_SHIFT) \& SWAP_FLAG_PRIO_MASK$. These functions may only be used by the superuser.

PRIORITY

Each swap area has a priority, either high or low. The default priority is low. Within the low-priority areas, newer areas are of even lower priority than older areas.

All priorities set with `swapflags` are high priority, higher than the default. They may have any non-negative value chosen by the caller. Higher numbers mean higher priority.

Swap pages are allocated from areas in priority order, highest priority first. For areas with different priorities, a higher-priority area is exhausted before using a lower-priority area. If two or more areas have the same priority, and that is the highest priority available, pages are allocated on a round-robin basis between them.

As of Linux 1.3.6, the kernel usually follows these rules, but there are exceptions.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

Many other errors besides the following can occur if `path` is not valid:

<code>EPERM</code>	The user is not the superuser, or more than <code>MAX_SWAPFILES</code> (defined to be 8 in Linux 1.3.6) are in use.
<code>EINVAL</code>	Returned if <code>path</code> exists, but is neither a regular path nor a block device.
<code>ENOENT</code>	Returned if <code>path</code> does not exist.
<code>ENOMEM</code>	Returned if there is insufficient memory to start swapping.

CONFORMS TO

These functions are Linux specific.

NOTES

The partition or `path` must be prepared with `mkswap(8)`.

HISTORY

The second (`swapflags`) argument was introduced in Linux 1.3.2.

Linux 1.3.6, 22 July 1995

symlink

`symlink`—Makes a new name for a file

SYNOPSIS

```
#include <unistd.h>
int symlink(const char *oldpath, const char *newpath);
```

DESCRIPTION

`symlink` creates a symbolic link named `oldpath` that contains `newpath`.

Symbolic links are interpreted at runtime, as if the contents of the link were substituted into the path being followed to find a file or directory.

Symbolic links may contain `..` path components that (if used at the start of the link) refer to the parent directories of the one in which the link resides.

A symbolic link (also known as a *soft link*) can point to an existing file or to a nonexistent one; the latter case is known as a *dangling link*.

The permissions of a symbolic link are irrelevant; the ownership is ignored when following the link, but is checked when removal or renaming of the link is requested and the link is in a directory with the sticky bit set.

If `newpath` exists, it will not be overwritten.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

EPERM	The filesystem containing <code>pathname</code> does not support the creation of symbolic links.
EFAULT	<code>oldpath</code> or <code>newpath</code> points outside your accessible address space.
EACCES	Write access to the directory containing <code>newpath</code> is not allowed for the process's effective UID, or one of the directories in <code>newpath</code> did not allow search (execute) permission.
ENAMETOOLONG	<code>oldpath</code> or <code>newpath</code> was too long.
ENOENT	A directory component in <code>newpath</code> does not exist or is a dangling symbolic link, or <code>oldpath</code> is the empty string.
ENOTDIR	A component used as a directory in <code>newpath</code> is not, in fact, a directory.
ENOMEM	Insufficient kernel memory was available.
EROFS	The file is on a read-only filesystem.
EEXIST	<code>newpath</code> already exists.
ELoop	<code>newpath</code> contains a reference to a circular symbolic link—that is, a symbolic link whose expansion contains a reference to itself.
ENOSPC	The device containing the file has no room for the new directory entry.

NOTES

No checking of `oldpath` is done.

Deleting the name referred to by a `symlink` will actually delete the file (unless it also has other hard links). If this behavior is not desired, use `link`.

CONFORMS TO

SVID, AT&T, POSIX, BSD 4.3

BUGS

See `open(2)` regarding multiple files with the same name, and NFS.

sync

sync—Commits buffer cache to disk

SYNOPSIS

```
#include <unistd.h>
int sync(void);
```

DESCRIPTION

sync first commits inodes to buffers, and then buffers to disk.

RETURN VALUE

sync always returns 0.

CONFORMS TO

SVID, AT&T, X/OPEN, BSD 4.3

BUGS

According to the standard specification (for example, SVID), sync() schedules the writes, but it might return before the actual writing is done. However, since version 1.3.20, Linux does actually wait. (This still does not guarantee data integrity; modern disks have large caches.)

Linux 1.3.88, 15 April 1995

sysctl

sysctl—Reads/writes system parameters

SYNOPSIS

```
#include <unistd.h>
#include <linux/unistd.h>
#include <linux/sysctl.h>
_syscall1(int sysctl, struct __sysctl_args *args);
int sysctl(struct __sysctl_args *args);
```

DESCRIPTION

The sysctl call reads and/or writes kernel parameters—for example, the hostname or the maximum number of open files. The argument has the form

```
struct __sysctl_args {
    int *name; /* integer vector describing variable */
    int nlen; /* length of this vector */
    void *oldval; /* 0 or address where to store old value */
    size_t *oldlenp; /* available room for old value,
```

```

        overwritten by actual size of old value */
void *newval; /* 0 or address of new value */
size_t newlen; /* size of new value */
};

```

This call does a search in a tree structure, possibly resembling a directory tree under `/proc/sys`, and, if the requested item is found, calls some appropriate routine to read or modify the value.

EXAMPLE

```

#include <linux/unistd.h>
#include <linux/types.h>
#include <linux/sysctl.h>

_syscall1(int, _sysctl, struct __sysctl args *, args);
int sysctl(int *name, int nlen, void *oldval, size_t *oldlenp,
          void *newval, size_t newlen)
{
    struct __sysctl__args args={name,nlen,oldval,oldlenp,newval,newlen};
    return _sysctl(&args);
}

#define SIZE(x) sizeof(x)/sizeof(x[0])
#define OSNAMESZ 100

char osname[OSNAMESZ];
int osnamelth;
int name[] = { CTL_KERN, KERN_OSTYPE };

main(){
    osnamelth = SIZE(osname);
    if (sysctl(name, SIZE(name), osname, &osnamelth, 0, 0))
        perror("sysctl");
    else
        printf("This machine is running %s\n", osnamelth, osname);
    return 0;
}

```

RETURN VALUES

Upon successful completion, `sysctl` returns 0. Otherwise, a value of -1 is returned, and `errno` is set to indicate the error.

ERRORS

ENOTDIR	name was not found.
EPERM	No search permission for one of the encountered directories, or no read permission where <code>oldval</code> was nonzero, or no write permission where <code>newval</code> was nonzero.
EFAULT	The invocation asked for the previous value by setting <code>oldval</code> non-NULL, but allowed zero room in <code>oldlenp</code> .

CONFORMS TO

This call is Linux specific.

HISTORY

A `sysctl` call has been present in Linux since version 1.3.57. It originated in BSD-4.4. Only Linux has the `/proc/sys` mirror, and the object-naming schemes differ between Linux and BSD 4.4, but the declaration of the `sysctl(2)` function is the same in both.

BUGS

Not all available objects are properly documented.

It is not yet possible to change operating system by writing to `/proc/sys/kernel/ostype`.

SEE ALSO

`proc(5)`

Linux 1.3.85, 11 April 1996

sysfs

`sysfs`—Gets filesystem type information

SYNOPSIS

```
int sysfs(int option, const char * fsname);
int sysfs(int option, unsigned int fs_index, char * buf);
int sysfs(int option);
```

DESCRIPTION

`sysfs` returns information about the filesystem types currently present in the kernel. The specific form of the `sysfs` call and the information returned depend on the option in effect. You can

- Translate the filesystem identifier string `fsname` into a filesystem type index.
- Translate the filesystem type index `fs_index` into a null-terminated filesystem identifier string. This string will be written to the buffer pointed to by `buf`. Make sure that `buf` has enough space to accept the string.
- Return the total number of filesystem types currently present in the kernel.

The numbering of the filesystem type indexes begins with 0.

RETURN VALUE

On success, `sysfs` returns the filesystem index for the first option, 0 for the second option, and the number of currently configured filesystems for the third option. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

EINVAL	<code>fsname</code> is not a valid filesystem type identifier; <code>fs_index</code> is out of bounds; <code>option</code> is invalid.
EFAULT	Either <code>fsname</code> or <code>buf</code> is outside your accessible address space.

CONFORMS TO

Linux 1.3.16, 9 August 1995

sysinfo

`sysinfo`—Returns information on overall system statistics

SYNOPSIS

As of Linux 0.99.10 and image release 4.4,

```
#include <linux/kernel.h>
#include <linux/sys.h>
int sysinfo(struct sysinfo *info);
```

DESCRIPTION

`sysinfo` returns information in the following structure:

```
struct sysinfo {
    long uptime;           /* Seconds since boot */
    unsigned long loads[3]; /* 1, 5, and 15 minute load averages */
    unsigned long totalram; /* Total usable main memory size */
    unsigned long freeram; /* Available memory size */
    unsigned long sharedram; /* Amount of shared memory */
    unsigned long bufferram; /* Memory used by buffers */
    unsigned long totalswap; /* Total swap space size */
    unsigned long freeswap; /* swap space still available */
    unsigned short procs; /* Number of current processes */
    char _f[22];          /* Pads structure to 64 bytes */
};
```

`sysinfo` provides a simple way of getting overall system statistics. This is more portable than reading `/dev/kmem`.

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

EFAULT The pointer to `struct sysinfo` is invalid.

CONFORMS TO

This function is Linux specific.

BUGS

The Linux DLL 4.4.1 libraries do not contain a proper prototype for this function.

Linux 0.99.10, 24 July 1993

syslog

`syslog`—Reads and/or clears kernel message ring buffer; sets `console_loglevel`

SYNOPSIS

```
#include <unistd.h>
#include <linux/unistd.h>
_syscall3(int syslog, int type, char *bufp, int len);
int syslog(int type, char *bufp, int len);
```

DESCRIPTION

This is probably not the function you are interested in. Look at `syslog(3)` for the C library interface. This page only documents the bare kernel system call interface.

The `type` argument determines the action taken by `syslog`.

From `kernel/printk.c`:

Valid commands to `syslog` are

- `0`—Close the log. Currently a NOP.
- `1`—Open the log. Currently a NOP.
- `2`—Read from the log.

- 3—Read up to the last 4KB of messages in the ring buffer.
- 4—Read and clear last 4KB of messages in the ring buffer.
- 5—Clear ring buffer.
- 6—Disable `printks` to console.
- 7—Enable `printks` to console.
- 8—Set `level` of messages printed to console.

Only function 3 is allowed to non-root processes.

THE KERNEL LOG BUFFER

The kernel has a cyclic buffer of length `LOG_BUF_LEN` (4096) in which messages given as argument to the kernel function `printk()` are stored (regardless of their `loglevel`).

The call `syslog (2,buf,len)` waits until this kernel log buffer is nonempty, and then reads at most `len` bytes into the buffer `buf`. It returns the number of bytes read. Bytes read from the log disappear from the log buffer; the information can only be read once. This is the function executed by the kernel when a user program reads `/proc/kmsg`.

The call `syslog (3,buf,len)` will read the last `len` bytes from the log buffer (nondestructively), but will not read more than was written into the buffer since the last “clear ring buffer” command (which does not clear the buffer at all). It returns the number of bytes read.

The call `syslog (4,buf,len)` does precisely the same, but also executes the “clear ring buffer” command.

The call `syslog (5,dummy,idummy)` only executes the “clear ring buffer” command.

THE LOGLEVEL

The kernel routine `printk()` will print a message on the console only if it has a `loglevel` less than the value of the variable `console_loglevel` (initially `DEFAULT_CONSOLE_LOGLEVEL` (7), but set to 10 if the kernel command line contains the word `debug`, and to 15 in case of a kernel fault—the 10 and 15 are just silly, and are equivalent to 8). This variable is set (to a value in the range 1–8) by the call `syslog (8,dummy,value)`. The call `syslog (type,dummy,idummy)` with `type` equal to 6 or 7, sets it to 1 (kernel panics only) or 7 (all except debugging messages), respectively.

Every text line in a message has its own `loglevel`. This level is `DEFAULT_MESSAGE_LOGLEVEL - 1` (6) unless the line starts with `<d>` where `d` is a digit in the range 1–7, in which case the level is `d`. The conventional meaning of the `loglevel` is defined in `<linux/kernel.h>` as follows:

```
#define KERN_EMERG    "<0>" /* system is unusable          */
#define KERN_ALERT   "<1>" /* action must be taken immediately */
#define KERN_CRIT    "<2>" /* critical conditions             */
#define KERN_ERR     "<3>" /* error conditions                */
#define KERN_WARNING "<4>" /* warning conditions              */
#define KERN_NOTICE  "<5>" /* normal but significant condition */
#define KERN_INFO    "<6>" /* informational                   */
#define KERN_DEBUG   "<7>" /* debug-level messages            */
```

RETURN VALUE

In case of error, `-1` is returned, and `errno` is set. On success, for `type` equal to 2, 3, or 4, `syslog()` returns the number of bytes read; otherwise, it returns 0.

ERRORS

<code>EPERM</code>	An attempt was made to change <code>console_loglevel</code> or clear the kernel message ring buffer by a process without root permissions.
<code>EINVAL</code>	Bad parameters.
<code>ERESTARTSYS</code>	System call was interrupted by a signal—nothing was read.

CONFORMS TO

This system call is Linux specific.

termios, tcgetattr, tcsetattr, tcsendbreak, tcdrain, tcflush, tcflow, cfgetospeed, cfgetispeed, cfsetispeed, cfsetospeed, tcgetpgrp, tcsetpgrp

termios, tcgetattr, tcsetattr, tcsendbreak, tcdrain, tcflush, tcflow, cfgetospeed, cfgetispeed, cfsetispeed, cfsetospeed, tcgetpgrp, tcsetpgrp—Get and set terminal attributes, do line control, get and set baud rate, get and set terminal foreground process group ID

SYNOPSIS

```
#include <termios.h>
#include <unistd.h>
int tcgetattr ( int fd, struct termios *termios_p );
int tcsetattr ( int fd, int optional_actions, struct termios *termios_p );
int tcsendbreak ( int fd, int duration );
int tcdrain ( int fd );
int tcflush ( int fd, int queue_selector );
int tcflow ( int fd, int action );
speed_t cfgetospeed ( struct termios *termios_p );
int cfsetospeed ( struct termios *termios_p, speed_t speed );
speed_t cfgetispeed ( struct termios *termios_p );
int cfsetispeed ( struct termios *termios_p, speed_t speed );
pid_t tcgetpgrp ( int fd );
int tcsetpgrp ( int fd, pid_t pgrp_id );
```

DESCRIPTION

The termios functions describe a general terminal interface that is provided to control asynchronous communications ports.

Many of the functions described here have a `termios_p` argument that is a pointer to a `termios` structure. This structure contains the following members:

```
tcflag_t c_iflag; /* input modes */
tcflag_t c_oflag; /* output modes */
tcflag_t c_cflag; /* control modes */
tcflag_t c_lflag; /* local modes */
cc_t c_cc[NCCS]; /* control chars */
```

The following are the `c_iflag` flag constants:

IGNBRK	Ignore BREAK condition on input.
BRKINT	If IGNBRK is not set, generate SIGINT on BREAK condition; otherwise, read BREAK as character <code>\0</code> .
IGNPAR	Ignore framing errors and parity errors.
PARMRK	If IGNPAR is not set, prefix a character with a parity error or framing error with <code>\377 \0</code> . If neither IGNPAR nor PARMRK is set, read a character with a parity error or framing error as <code>\0</code> .
INPCK	Enable input parity checking.

termios, tcgetattr, tcsetattr, tcsendbreak, tcdrain, tclflush, tcfLOW, cfgetospeed, cfgetispeed, cfsetispeed, cfsetospeed, tcgetpgrp, tcsetpgrp

ISTRIP	Strip off the eighth bit.
INLCR	Translate NL to CR on input.
IGNCR	Ignore carriage return on input.
ICRNL	Translate carriage return to newline on input (unless IGNCR is set).
IUCLC	Map uppercase characters to lowercase on input.
IXON	Enable XON/XOFF flow control on output.
IXANY	Enable any character to restart output.
IXOFF	Enable XON/XOFF flow control on input IMAXBEL ring bell when input queue is full.

The following are the `c_oflag` flag constants:

OPOST	Enable implementation-defined output processing.
OLCUC	Map lowercase characters to uppercase on output.
ONLCR	Map NL to CR-NL on output.
OCRNL	Map CR to NL on output.
ONOCR	Don't output CR at column 0.
ONLRET	Don't output CR.
OFILL	Send fill characters for a delay rather than use a timed delay.
OFDEL	Fill character is ASCII DEL. If unset, fill character is ASCII NUL.
NLDLY	Newline delay mask. Values are NL0 and NL1.
CRDLY	Carriage-return delay mask. Values are CR0, CR1, CR2, and CR3.
TABDLY	Horizontal-tab delay mask. Values are TAB0, TAB1, TAB2, TAB3, and XTABS. A value of XTABS expands tabs to spaces (with tab stops every eight columns).
BSDLY	Backspace delay mask. Values are BS0 and BS1.
VTDLY	Vertical-tab delay mask. Values are VT0 and VT1.
FFDLY	Form-feed delay mask. Values are FF0 and FF1.

The following are the `c_cflag` flag constants:

CSIZE	Character size mask. Values are CS5, CS6, CS7, and CS8.
CSTOPB	Set two stop bits rather than one.
CREAD	Enable receiver.
PARENB	Enable parity generation on output and parity checking for input.
PARODD	Parity for input and output is odd.
HUPCL	Lower modem control lines after last process closes the device (hangs up).
CLOCAL	Ignore modem control lines.
CIBAUD	Mask for input speeds (not used).
CRTSCTS	Flow control.

The following are the `c_lflag` flag constants:

ISIG	When any of the characters INTR, QUIT, SUSP, or DSUSP are received, generate the corresponding signal.
ICANON	Enables canonical mode. This allows the special characters EOF, EOL, EOL2, ERASE, KILL, REPRINT, STATUS, and WERASE, and also buffers by lines.
XCASE	If ICANON is also set, terminal is uppercase only. Input is converted to lowercase, except for characters preceded by \. On output, uppercase characters are preceded by \, and lowercase characters are converted to uppercase.
ECHO	Echo input characters.

ECHOE	If ICANON is also set, the ERASE character erases the preceding input character, and WERASE erases the preceding word.
ECHOK	If ICANON is also set, the KILL character erases the current line.
ECHONL	If ICANON is also set, echo the NL character even if ECHO is not set.
ECHOCTL	If ECHO is also set, ASCII control signals other than TAB, NL, START, and STOP are echoed as Ctrl+ <i>X</i> , where <i>X</i> is the character with ASCII code 0x10 greater than the control signal. For example, character 0x28 (BS) is echoed as Ctrl+H.
ECHOPRT	If ICANON and IECHO are also set, characters are printed as they are being erased.
ECHOKE	If ICANON is also set, KILL is echoed by erasing each character on the line, as specified by ECHOE and ECHOPRT.
FLUSHO	Output is being flushed. This flag is toggled by typing the DISCARD character.
NOFLSH	Disables flushing of the input and output queues when generating the SIGINT and SIGQUIT signals, and flushing of the input queue when generating the SIGSUSP signal.
TOSTOP	Sends the SIGTTOU signal to the process group of a background process that tries to write to its controlling terminal.
PENDIN	All characters in the input queue are reprinted when the next character is read. (<i>bash</i> handles typeahead this way.)
IEXTEN	Enable implementation-defined input processing.

`tcgetattr()` gets the parameters associated with the object referred to by `fd` and stores them in the `termios` structure referenced by `termios_p`. This function may be invoked from a background process; however, the terminal attributes may be subsequently changed by a foreground process.

`tcsetattr()` sets the parameters associated with the terminal (unless support is required from the underlying hardware that is not available) from the `termios` structure referred to by `termios_p`. `optional_actions` specifies when the changes take effect:

TCSANOW	The change occurs immediately.
TCSADRAIN	The change occurs after all output written to <code>fd</code> has been transmitted. This function should be used when changing parameters that affect output.
TCSAFLUSH	The change occurs after all output written to the object referred to by <code>fd</code> has been transmitted, and all input that has been received but not read will be discarded before the change is made.

`tcsendbreak()` transmits a continuous stream of zero-valued bits for a specific duration, if the terminal is using asynchronous serial data transmission. If `duration` is 0, it transmits zero-valued bits for at least 0.25 seconds, and not more than 0.5 seconds. If `duration` is not 0, it sends zero-valued bits for `duration * N` seconds, where *N* is at least 0.25, and not more than 0.5.

If the terminal is not using asynchronous serial data transmission, `tcsendbreak()` returns without taking any action.

`tcdrain()` waits until all output written to the object referred to by `fd` has been transmitted.

`tcflush()` discards data written to the object referred to by `fd` but not transmitted, or data received but not read, depending on the value of `queue_selector`:

TCIFLUSH	Flushes data received but not read.
TCOFLUSH	Flushes data written but not transmitted.
TCIOFLUSH	Flushes both data received but not read and data written but not transmitted.

`tcflow()` suspends transmission or reception of data on the object referred to by `fd`, depending on the value of `action`:

TCOOFF	Suspends output.
TCOON	Restarts suspended output.
TCIOFF	Transmits a STOP character, which stops the terminal device from transmitting data to the system.
TCION	Transmits a START character, which starts the terminal device transmitting data to the system.

The default on open of a terminal file is that neither its input nor its output is suspended.

The baud rate functions are provided for getting and setting the values of the input and output baud rates in the `termios` structure. The new values do not take effect until `tcsetattr()` is successfully called.

Setting the speed to `B0` instructs the modem to hang up. The actual bit rate corresponding to `B38400` may be altered with `setserial(8)`.

The input and output baud rates are stored in the `termios` structure.

`cfgetospeed()` returns the output baud rate stored in the `termios` structure pointed to by `termios_p`.

`cfsetospeed()` sets the output baud rate stored in the `termios` structure pointed to by `termios_p` to `speed`, which must be one of these constants:

`B0`
`B50`
`B75`
`B110`
`B134`
`B150`
`B200`
`B300`
`B600`
`B1200`
`B1800`
`B2400`
`B4800`
`B9600`
`B19200`
`B38400`
`B57600`
`B115200`
`B230400`

The zero baud rate, `B0`, is used to terminate the connection. If `B0` is specified, the modem control lines will no longer be asserted. Normally, this will disconnect the line. `CBAUDEX` is a mask for the speeds beyond those defined in POSIX.1 (57600 and later). Thus, `B57600 & CBAUDEX` is nonzero.

`cfgetispeed()` returns the input baud rate stored in the `termios` structure.

`cfsetispeed()` sets the input baud rate stored in the `termios` structure to `speed`. If the input baud rate is set to `0`, it will be equal to the output baud rate.

`tcgetpgrp()` returns the process group ID of the foreground processing group, or `-1` on error.

`tcsetpgrp()` sets the process group ID to `pgrp_id`. `pgrp_id` must be the ID of a process group in the same session.

RETURN VALUES

`cfgetispeed()` returns the input baud rate stored in the `termios` structure.

`cfgetospeed()` returns the output baud rate stored in the `termios` structure.

`tcgetpgrp()` returns the process group ID of foreground processing group, or `-1` on error.

All other functions return

0 On success.
-1 on failure (and set `errno` to indicate the error).

time

`time`—Gets time in seconds

SYNOPSIS

```
#include <time.h>
time_t time(time_t *t);
```

DESCRIPTION

`time` returns the time since 00:00:00 GMT, January 1, 1970, measured in seconds.

If `t` is non null, the return value is also stored in the memory pointed to by `t`.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

(Under BSD 4.3, this call is made obsolete by `gettimeofday(2)`.)

times

`times`—Gets process times

SYNOPSIS

```
#include <sys/times.h>
clock_t times(struct tms *buf);
```

DESCRIPTION

`times` stores the current process times in `buf`.

`struct tms` is as defined in `/usr/include/sys/times.h`:

```
struct tms {
    time_t tms_utime; /* user time */
    time_t tms_stime; /* system time */
    time_t tms_cutime; /* user time of children */
    time_t tms_cstime; /* system time of children */
};
```

`times` returns the number of clock ticks that have elapsed since the system has been up.

truncate, ftruncate

truncate, ftruncate—Truncate a file to a specified length

SYNOPSIS

```
#include <unistd.h>
int truncate(const char *path, size_t length);
int ftruncate(int fd, size_t length);
```

DESCRIPTION

truncate causes the file named by path or referenced by fd to be truncated to at most length bytes in size. If the file previously was larger than this size, the extra data is lost. With ftruncate, the file must be open for writing.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and errno is set appropriately.

ERRORS

The errors for truncate are

ENOTDIR	A component of the path prefix is not a directory.
EINVAL	The pathname contains a character with the high-order bit set.
ENAMETOOLONG	A component of a pathname exceeded 255 characters, or an entire pathname exceeded 1,023 characters.
ENOENT	The named file does not exist.
EACCES	Search permission is denied for a component of the path prefix.
EACCES	The named file is not writeable by the user.
ELOOP	Too many symbolic links were encountered in translating the pathname.
EISDIR	The named file is a directory.
EROFS	The named file resides on a read-only filesystem.
ETXTBSY	The file is a pure procedure (shared text) file that is being executed.
EIO	An I/O error occurred updating the inode.
EFAULT	path points outside the process's allocated address space.

The errors for ftruncate are

EBADF	fd is not a valid descriptor.
EINVAL	fd references a socket, not a file.
EINVAL	fd is not open for writing.

HISTORY

These function calls appeared in BSD 4.2.

BUGS

These calls should be generalized to allow ranges of bytes in a file to be discarded.

uname

`uname`—Gets name and information about the current kernel

SYNOPSIS

```
#include <sys/utsname.h>
int uname(struct utsname *buf);
```

DESCRIPTION

`uname` returns system information in `buf`. The `utsname` struct is as defined in `/usr/include/sys/utsname.h`:

```
struct utsname {
    char sysname[65];
    char nodename[65];
    char release[65];
    char version[65];
    char machine[65];
    char domainname[65];
};
```

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

EFAULT buf is not valid.

none

none—Undocumented system calls

SYNOPSIS

Undocumented system calls.

DESCRIPTION

As of Linux 1.3.88, there are 163 system calls listed in `/usr/include/asm/unistd.h`. This man page mentions those calls that are implemented in the kernel but not yet documented in man pages. Some of these calls do not yet have prototypes in the libc include files.

SOLICITATION

If you have information about these system calls, please look in the kernel source code, write a man page (using a style similar to that of the other Linux section 2 man pages), and send it to `aeb@cwil.n1` for inclusion in the next man page release from the Linux Documentation Project.

STATUS

Undocumented are `msync`, `readv`, `writev`, `getsid`, `fdatasync`, `sysctl`, `sched_setparam`, `sched_getparam`, `sched_setscheduler`, `sched_getscheduler`, `sched_yield`, `sched_get_priority_max`, `sched_get_priority_min`, `sched_rr_get_interval`.

afs_syscall, break, gtty, lock, mpx, prof, quotactl, stty, ustat

afs_syscall, break, gtty, lock, mpx, prof, quotactl, stty, ustat—Unimplemented system calls

SYNOPSIS

Unimplemented system calls.

DESCRIPTION

These system calls are not implemented in the Linux 1.2.4 kernel.

RETURN VALUE

These system calls always return `-1` and set `errno` to `ENOSYS`.

SEE ALSO

`obsolete(2)`, `undocumented(2)`

Linux 1.2.4, 15 April 1995

unlink

`unlink`—Deletes a name and possibly the file it refers to

SYNOPSIS

```
#include <unistd.h>
int unlink(const char *pathname);
```

DESCRIPTION

`unlink` deletes a name from the filesystem. If that name was the last link to a file and no processes have the file open, the file is deleted, and the space it was using is made available for reuse.

If the name was the last link to a file but any processes still have the file open, the file will remain in existence until the last file descriptor referring to it is closed.

If the name referred to a symbolic link, the link is removed.

If the name referred to a socket, fifo, or device, the name for it is removed but processes that have the object open can continue to use it.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

EFAULT	<code>pathname</code> points outside your accessible address space.
EACCES	Write access to the directory containing <code>pathname</code> is not allowed for the process's effective UID, or one of the directories in <code>pathname</code> did not allow search (execute) permission.
EPERM	The directory containing <code>pathname</code> has the sticky bit (<code>S_ISVTX</code>) set, and the process's effective UID is neither the UID of the file to be deleted nor that of the directory containing it, or <code>pathname</code> is a directory.
ENAMETOOLONG	<code>pathname</code> was too long.
ENOENT	A directory component in <code>pathname</code> does not exist or is a dangling symbolic link.
ENOTDIR	A component used as a directory in <code>pathname</code> is not, in fact, a directory.
EISDIR	<code>pathname</code> refers to a directory.
ENOMEM	Insufficient kernel memory was available.
EROFS	<code>pathname</code> refers to a file on a read-only filesystem.

CONFORMS TO

SVID, AT&T, POSIX, X/OPEN, BSD 4.3

BUGS

Infelicities in the protocol underlying NFS can cause the unexpected disappearance of files that are still being used.

uselib

uselib—Selects shared library

SYNOPSIS

```
#include <unistd.h>
int uselib(const char *library);
```

DESCRIPTION

uselib selects the shared library binary that will be used by this process.

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

In addition to all the error codes returned by `open(2)` and `mmap(2)`, the following may also be returned:

ENOEXEC	The file specified by <code>library</code> is not executable, or does not have the correct magic numbers.
EACCES	The library specified by <code>library</code> is not readable.

CONFORMS TO

uselib() is Linux specific.

SEE ALSO

`open(2)`, `mmap(2)`, `ldd(1)`, `gcc(1)`, `ar(1)`, `ld(1)`

Linux 0.99.11, 24 July 1993

ustat

ustat—Gets filesystem statistics

SYNOPSIS

```
#include <sys/types.h>
int ustat(dev_t dev, struct ustat * ubuf);
```

DESCRIPTION

ustat returns information about a mounted filesystem. `dev` is a device number identifying a device containing a mounted filesystem. `ubuf` is a pointer to a `ustat` structure that contains the following members:

```
daddr_t f_tfree; /* Total free blocks */
ino_t f_tinode; /* Number of free inodes */
char f_fname[6]; /* Filsys name */
char f_fpack[6]; /* Filsys pack name */
```

The last two fields, `f_fname` and `f_fpack`, are not implemented and will always be filled with null characters.

RETURN VALUE

On success, 0 is returned, and the `ustat` structure pointed to by `ubuf` will be filled in. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

EINVAL	<code>dev</code> does not refer to a device containing a mounted filesystem.
EFAULT	<code>ubuf</code> points outside of your accessible address space.
ENOSYS	The mounted filesystem referenced by <code>dev</code> does not support this operation, or any version of Linux before 1.3.16.

NOTES

`ustat` has been provided for compatibility only. All new programs should use `statfs(2)` instead.

HISTORY

`ustat` was first implemented in Linux 1.3.16. All versions of Linux before 1.3.16 will return `ENOSYS`.

CONFORMS TO

System V

SEE ALSO

Linux 1.3.16, 9 August 1995

utime, utimes

`utime`, `utimes`—Change access and/or modification times of an inode

SYNOPSIS

```
#include <sys/types.h>
#include <utime.h>
int utime(const char *filename, struct utimbuf *buf);
#include <sys/time.h>
int utimes(char *filename, struct timeval *tvp);
```

DESCRIPTION

`utime` changes the access and modification times of the inode specified by `filename` to the `actime` and `modtime` fields of `buf`, respectively. If `buf` is `NULL`, the access and modification times of the file are set to the current time. The `utimbuf` structure is

```
struct utimbuf {
    time_t actime; /* access time */
    time_t modtime; /* modification time */
};
```

In the Linux DLL 4.4.1 libraries, `utimes` is just a wrapper for `utime`, `tvp[0].tv_sec` is `actime`, and `tvp[1].tv_sec` is `modtime`. The `timeval` structure is

```
struct timeval {
    long tv_sec; /* seconds */
    long tv_usec; /* microseconds */
};
```

RETURN VALUE

On success, `0` is returned. On error, `-1` is returned, and `errno` is set appropriately.

ERRORS

Other errors may occur.

EACCESS	Permission to write the file is denied.
ENOENT	file name does not exist.

CONFORMS TO

utime: SVID, POSIX
utimes: BSD4.3

vm86

vm86—Enters virtual 8086 mode

SYNOPSIS

```
#include <sys/vm86.h>
int vm86(struct vm86_struct * info);
```

DESCRIPTION

Enter VM86 mode with information as specified in `info`:

```
struct vm86_struct {
    struct vm86_regs regs;
    unsigned long flags;
```

```

        unsigned long screen_bitmap;
};

struct vm86_regs {
/*
 * normal regs, with special meaning for the segment descriptors..
 */
    long ebx;
    long ecx;
    long edx;
    long esi;
    long edi;
    long ebp;
    long eax;
    long __null_ds;
    long __null_es;
    long __null_fs;
    long __null_gs;
    long orig_eax;
    long eip;
    long cs;
    long eflags;
    long esp;
    long ss;

/*
 * these are specific to v86 mode:
 */
    long es;
    long ds;
    long fs;
    long gs;
};

these are specific to v86 mode:

/
long es;
long ds;
long fs;
long gs;
};

```

RETURN VALUE

On success, 0 is returned. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

`EPERM` Saved kernel stack exists.

Linux 0.99.11, 24 July 1993

wait, waitpid

`wait, waitpid`—Wait for process termination

SYNOPSIS

```

#include <sys/types.h>
#include <sys/wait.h>

```

```
pid_t wait(int *status)
pid_t waitpid(pid_t pid,int*status,int options);
```

DESCRIPTION

The `wait` function suspends execution of the current process until a child has exited, or until a signal is delivered whose action is to terminate the current process or to call a signal-handling function. If a child has already exited by the time of the call (a so-called *zombie* process), the function returns immediately. Any system resources used by the child are freed.

The `waitpid` function suspends execution of the current process until a child as specified by the `pid` argument has exited, or until a signal is delivered whose action is to terminate the current process or to call a signal-handling function. Just as with `wait`, if a child requested by `pid` has already exited by the time of the call, the function returns immediately. Any system resources used by the child are freed.

The value of `pid` can be one of the following:

< -1	Wait for any child process whose process group ID is equal to the absolute value of <code>pid</code> .
-1	Wait for any child process; this is the same behavior that <code>wait</code> exhibits.
0	Wait for any child process whose process group ID is equal to that of the calling process.
> 0	Wait for the child whose process ID is equal to the value of <code>pid</code> .

The value of `options` is an OR of zero or more of the following constants:

WNOHANG	Return immediately if no child has exited.
WUNTRACED	Also return for children that are stopped and whose status has not been reported.

If `status` is not NULL, `wait` or `waitpid` stores status information in the location pointed to by `statloc`.

This status can be evaluated with the following macros (these macros take the `stat` buffer as an argument—not a pointer to the buffer!):

WIFEXITED(<code>status</code>)	Is nonzero if the child exited normally.
WEXITSTATUS(<code>status</code>)	Evaluates to the least significant eight bits of the return code of the child that terminated, which may have been set as the argument to a call to <code>exit()</code> or as the argument for a return statement in the main program. This macro can only be evaluated if <code>WIFEXITED</code> returned nonzero.
WIFSIGNALED(<code>status</code>)	Returns true if the child process exited because of a signal that was not caught.
WTERMSIG(<code>status</code>)	Returns the number of the signal that caused the child process to terminate. This macro can only be evaluated if <code>WIFSIGNALED</code> returned nonzero.
WIFSTOPPED(<code>status</code>)	Returns true if the child process that caused the return is currently stopped; this is only possible if the call was done using <code>WUNTRACED</code> .
WSTOPSIG(<code>status</code>)	Returns the number of the signal that caused the child to stop. This macro can only be evaluated if <code>WIFSTOPPED</code> returned nonzero.

RETURN VALUE

The process ID of the child that exited returns `-1` on error or `0` if `WNOHANG` was used and no child was available (in which case `errno` is set to an appropriate value).

ERRORS

ECHILD	If the child process specified in <code>pid</code> does not exist.
EPERM	If the effective user ID of the calling process does not match that of the process being waited for, and the effective user ID of the calling process is not that of the superuser.
ERESTARTSYS	If <code>WNOHANG</code> was not set and an unblocked signal or a <code>SIGCHLD</code> was caught; this is an extension to the POSIX.1 standard.

CONFORMS TO

POSIX.1

SEE ALSO

Linux, 24 July 1993

wait3, wait4

wait3, wait4—Wait for process termination, BSD style

SYNOPSIS

```
#define _USE_BSD
#include <sys/types.h>
#include <sys/resource.h>
#include <sys/wait.h>
pid_t wait3(int *status,int options,
struct rusage *rusage);
pid_t wait4(pid_t pid,int*status,int options,
struct rusage *rusage);
```

DESCRIPTION

The `wait3` function suspends execution of the current process until a child has exited, or until a signal is delivered whose action is to terminate the current process or to call a signal-handling function. If a child has already exited by the time of the call (a zombie process), the function returns immediately. Any system resources used by the child are freed.

The `wait4` function suspends execution of the current process until a child as specified by the `pid` argument has exited, or until a signal is delivered whose action is to terminate the current process or to call a signal-handling function. If a child as requested by `pid` has already exited by the time of the call (a zombie process), the function returns immediately. Any system resources used by the child are freed.

The value of `pid` can be one of the following:

< -1	Wait for any child process whose process group ID is equal to the absolute value of <code>pid</code> .
-1	Wait for any child process; this is equivalent to calling <code>wait3</code> .
0	Wait for any child process whose process group ID is equal to that of the calling process.
> 0	Wait for the child whose process ID is equal to the value of <code>pid</code> .

The value of `options` is an exclusive OR of zero or more of the following constants:

WNOHANG	Return immediately if no child is there to be waited for.
WUNTRACED	Also return for children that are stopped and whose status has not been reported.

If `status` is not NULL, `wait3` and `wait4` store status information in the location pointed to by `statloc`.

This status can be evaluated with the following macros:

WIFEXITED(*status)	Is nonzero if the child exited normally.
WEXITSTATUS(*status)	Evaluates to the least significant eight bits of the return code of the child that terminated, which may have been set as the argument to a call to <code>exit</code> or as the argument for a <code>return</code> statement in the main program. This macro can only be evaluated if <code>WIFEXITED</code> returned nonzero.
WIFSIGNALED(*status)	Returns true if the child process exited because of a signal that was not caught.
WTERMSIG(*status)	Returns the number of the signal that caused the child process to terminate. This macro can only be evaluated if <code>WIFSIGNALED</code> returned nonzero.

WIFSTOPPED(*status)	Returns true if the child process that caused the return is currently stopped; this is only possible if the call was done using WUNTRACED.
WSTOPSIG(*status)	Returns the number of the signal that caused the child to stop. This macro can only be evaluated if WIFSTOPPED returned nonzero. If <code>rusage</code> is not NULL, the <code>struct rusage</code> as defined in <code><sys/resource.h></code> it points to will be filled with accounting information. See <code>getrusage(2)</code> for details.

RETURN VALUE

These calls return the process ID of the child that exited, `-1` on error, or `0` if `WNOHANG` was used and no child was available (in which case `errno` will be set appropriately).

ERRORS

ECHILD	If the child process specified in <code>pid</code> does not exist.
EPERM	If the effective user ID of the calling process does not match that of the process being waited for, and the effective user ID of the calling process is not that of the superuser.
ERESTARTSYS	If <code>WNOHANG</code> was not set and an unblocked signal or a <code>SIGCHLD</code> was caught; this is an extension to the POSIX.1 standard.

Linux, 24 July 1993

write

`write`—Writes to a file descriptor

SYNOPSIS

```
#include <unistd.h>
ssize_t write(int fd, const void *buf, size_t count);
```

DESCRIPTION

`write` writes up to `count` bytes to the file referenced by the file descriptor `fd` from the buffer starting at `buf`. POSIX requires that a `read()` that can be proved to occur after a `write()` returned returns the new data. Note that not all filesystems are POSIX conforming.

RETURN VALUE

On success, the number of bytes written is returned (`0` indicates nothing was written). On error, `-1` is returned, and `errno` is set appropriately. If `count` is `0` and the file descriptor refers to a regular file, `0` will be returned without causing any other effect. For a special file, the results are not portable.

ERRORS

EBADF	<code>fd</code> is not a valid file descriptor or is not open for writing.
EINVAL	<code>fd</code> is attached to an object that is unsuitable for writing.
EFAULT	<code>buf</code> is outside your accessible address space.

EPIPE	<code>fd</code> is connected to a pipe or socket whose reading end is closed. When this happens, the writing process will receive a SIGPIPE signal; if it catches, blocks, or ignores this, the error EPIPE is returned.
EAGAIN	Non-blocking I/O has been selected using <code>O_NONBLOCK</code> , and there was no room in the pipe or socket connected to <code>fd</code> to write the data immediately.
EINTR	The call was interrupted by a signal before any data was written.
ENOSPC	The device containing the file referred to by <code>fd</code> has no room for the data.

Other errors may occur, depending on the object connected to `fd`.

Part III:

Library Functions

Intro

DESCRIPTION

This chapter describes all the library functions, excluding the library functions described in Part 2, which implement system calls. The various function groups are identified by a letter that is appended to the chapter number:

- (3C) These functions—the functions from Chapter 2 and from Chapter 3S—are contained in the C standard library `libc`, which will be used by `cc(1)` by default.
- (3S) These functions are parts of the `stdio(3S)` library. They are contained in the standard C library `libc`.
- (3M) These functions are contained in the arithmetic library `libm`. They are used by the `f77(1)` FORTRAN compiler by default, but not by the `cc(1)` C compiler, which needs the option `-lm`.
- (3F) These functions are part of the FORTRAN library `libF77`. There are no special compiler flags needed to use these functions.
- (3X) Various special libraries. The manual pages documenting their functions specify the library names.

AUTHORS

Look at the header of the manual page for the author(s) and copyright conditions. Note that these can be different from page to page!

Linux, 13 December 1995

abort

`abort`—Causes abnormal program termination

SYNOPSIS

```
#include <stdlib.h>
void abort(void);
```

DESCRIPTION

The `abort()` function causes abnormal program termination unless the signal `SIGABORT` is caught and the signal handler does not return. If the `abort()` function causes program termination, all open streams are closed and flushed.

If the `SIGABORT` function is blocked or ignored, the `abort()` function will still override it.

RETURN VALUE

The `abort()` function never returns.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

`sigaction(2)`, `exit(3)`

GNU, 12 April 1993

abs

`abs`—Computes the absolute value of an integer

SYNOPSIS

```
#include <stdlib.h>
int abs(int j);
```

DESCRIPTION

The `abs()` function computes the absolute value of the integer argument `j`.

RETURN VALUE

Returns the absolute value of the integer argument.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

NOTES

Trying to take the absolute value of the most negative integer is not defined.

SEE ALSO

`ceil(3)`, `floor(3)`, `fabs(3)`, `labs(3)`, `rint(3)`

GNU, 6 June 1993

acos

`acos`—Arc cosine function

SYNOPSIS

```
#include <math.h>
double acos(double x);
```

DESCRIPTION

The `acos()` function calculates the arc cosine of `x`; that is the value whose cosine is `x`. If `x` falls outside the range -1 to 1 , `acos()` fails and `errno` is set.

RETURN VALUE

The `acos()` function returns the arc cosine in radians; the value is mathematically defined to be between 0 and π (inclusive).

ERRORS

EDOM `x` is out of range.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

acosh

`acosh`—Inverse hyperbolic cosine function

SYNOPSIS

```
#include <math.h>
double acosh(double x);
```

DESCRIPTION

The `acosh()` function calculates the inverse hyperbolic cosine of `x`; that is the value whose hyperbolic cosine is `x`. If `x` is less than 1.0, `acosh()` returns not-a-number (NaN), and `errno` is set.

ERRORS

EDOM `x` is out of range.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

alloca

`alloca`—Memory allocator

SYNOPSIS

```
#include <stdlib.h>
void *alloca( size_t size);
```

DESCRIPTION

The `alloca` function allocates `size` bytes of space in the stack frame of the caller. This temporary space is automatically freed on return.

RETURN VALUES

The `alloca` function returns a pointer to the beginning of the allocated space. If the allocation fails, a NULL pointer is returned.

CONFORMS TO

There is evidence that the `alloca` function appeared in 32v, pwb, pwb.2, 3bsd, and 4bsd. There is a man page for it in BSD 4.3. Linux uses the GNU version.

BUGS

The `alloca` function is machine dependent.

SEE ALSO

GNU, 29 November 1993

asin

`asin`—Arc sine function

SYNOPSIS

```
#include <math.h>
double asin(double x);
```

DESCRIPTION

The `asin()` function calculates the arc sine of x , which is the value whose sine is x . If x falls outside the range -1 to 1 , `asin()` fails and `errno` is set.

RETURN VALUE

The `asin()` function returns the arc sine in radians, and the value is mathematically defined to be between $-\pi/2$ and $\pi/2$ (inclusive).

ERRORS

EDOM x is out of range.

CONFORMS TO

13 June 1993

assert

`assert`—Abort the program if assertion is false

SYNOPSIS

```
#include <assert.h>
void assert (int expression);
```

DESCRIPTION

`assert()` prints an error message to standard output and terminates the program by calling `abort()` if `expression` is false (that is, evaluates to 0). This only happens when the macro `NDEBUG` is undefined.

RETURN VALUE

No value is returned.

CONFORMS TO

ISO9899 (ANSI C)

BUGS

`assert()` is implemented as a macro; if the expression tested has side effects, program behavior will be different depending on whether `NDEBUG` is defined. This may create Heisenbugs, which go away when debugging is turned on.

SEE ALSO

`exit(3)`, `abort(3)`

GNU, 4 April 1993

atan

`atan`—Arc tangent function

SYNOPSIS

```
#include <math.h>
double atan(double x);
```

DESCRIPTION

The `atan()` function calculates the arc tangent of `x`—that is, the value whose tangent is `x`.

RETURN VALUE

The `atan()` function returns the arc tangent in radians, and the value is mathematically defined to be between $-\pi/2$ and $\pi/2$ (inclusive).

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

atan2

`atan2`—Arc tangent function of two variables

SYNOPSIS

```
#include <math.h>
double atan2(double y, double x);
```

DESCRIPTION

The `atan2()` function calculates the arc tangent of the two variables, x and y . It is similar to calculating the arc tangent of y/x , except that the sines of both arguments are used to determine the quadrant of the result.

RETURN VALUE

The `atan2()` function returns the result in radians, which is between $-\pi$ and π (inclusive).

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

atexit

`atexit`—Register a function to be called at normal program termination

SYNOPSIS

```
#include <stdlib.h>
int atexit(void *function)(void);
```

DESCRIPTION

The `atexit()` function registers the given function to be called at normal program termination, whether via `exit(2)` or via return from the program's `main`. Functions so registered are called in the reverse order of their registration; no arguments are passed.

RETURN VALUE

The `atexit()` function returns the value `0` if successful; otherwise, the value `-1` is returned, and the global variable `errno` is set to indicate the error.

ERRORS

`ENOMEM` Insufficient memory available to add the function.

atof

`atof`—Convert a string to a double

SYNOPSIS

```
#include <stdlib.h>
double atof(const char *nptr);
```

DESCRIPTION

The `atof()` function converts the initial portion of the string pointed to by `nptr` to double. The behavior is the same as `strtod(nptr, (char **)NULL)`;

except that `atof()` does not detect errors.

RETURN VALUE

The converted value.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

GNU, 29 March 1993

atoi

`atoi`—Convert a string to an integer

SYNOPSIS

```
#include <stdlib.h>
int atoi(const char *nptr);
```

DESCRIPTION

The `atoi()` function converts the initial portion of the string pointed to by `nptr` to `int`. The behavior is the same as `strtol(nptr, (char **)NULL, 10)`;

except that `atoi()` does not detect errors.

RETURN VALUE

The converted value.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

`atof(3)`, `atol(3)`, `strtod(3)`, `strtol(3)`, `strtoul(3)`

atol

`atol`—Convert a string to a long integer

SYNOPSIS

```
#include <stdlib.h>
long atol(const char *nptr);
```

DESCRIPTION

The `atol()` function converts the initial portion of the string pointed to by `nptr` to `long`. The behavior is the same as `strtol(nptr, (char **)NULL, 10)`;

except that `atol()` does not detect errors.

RETURN VALUE

The converted value.

bcmp

`bcmp`—Compare byte strings

SYNOPSIS

```
#include <string.h>
int bcmp(const void *s1, const void *s2, int n);
```

DESCRIPTION

The `bcmp()` function compares the first `n` bytes of the strings `s1` and `s2`. If the two strings are equal, `bcmp()` returns 0; otherwise, it returns a nonzero result. If `n` is 0, the two strings are assumed to be equal.

RETURN VALUE

The `bcmp()` function returns 0 if the strings are equal; otherwise, a nonzero result is returned.

CONFORMS TO

4.3BSD. This function is deprecated—use `memcmp` in new programs.

SEE ALSO

`memcmp(3)`, `strcasemp(3)`, `strcmp(3)`, `strcoll(3)`, `strncmp(3)`, `strncasemp(3)`

GNU, 9 April 1993

bcopy

`bcopy`—Copy byte strings

SYNOPSIS

```
#include <string.h>
void bcopy (const void *src, void*dest, int n);
```

DESCRIPTION

The `bcopy()` function copies the first `n` bytes of the source string `src` to the destination string `dest`. If `n` is 0, no bytes are copied.

RETURN VALUE

The `bcopy()` function returns no value.

CONFORMS TO

4.3BSD. This function is deprecated—use `memcpy` in new programs.

SEE ALSO

GNU, 9 April 1993

bsearch

`bsearch`—Binary search of a sorted array.

SYNOPSIS

```
#include <stdlib.h>
void *bsearch(const void *key, const void *base, size_t nmemb,
size_t si ze,int(*compar)(const void *, const void *));
```

DESCRIPTION

The `bsearch()` function searches an array of `nmemb` objects, the initial member of which is pointed to by `base`, for a member that matches the object pointed to by `key`. The size of each member of the array is specified by `si ze`.

The contents of the array should be in ascending sorted order according to the comparison function referenced by `compar`.

The `compar` routine is expected to have two arguments that point to the `key` object and to an array member, in that order, and should return an integer less than, equal to, or greater than 0, respectively, if the `key` object is found to be less than, match, or be greater than the array member.

RETURN VALUE

The `bsearch()` function returns a pointer to a matching member of the array, or `NULL` if no match is found. If there are multiple elements that match the key, the element returned is unspecified.

CONFORMS TO

SVID 3, BSD 4.3, ISO 9899

bcmp, bcopy, bzero, memccpy, memchr, memcmp, memcpy, memfrob, memmem, memmove, memset

`bcmp, bcopy, bzero, memccpy, memchr, memcmp, memcpy, memfrob, memmem, memmove, memset`—Byte string operations

SYNOPSIS

```
#include <string.h>
int bcmp(const void *s1, const void *s2, int n);
void bcopy(const void *src, void *dest, int n);
void bzero(void *s, int n);
void *memccpy(void *dest, const void *src, int c, size_t n);
void *memchr(const void *s, int c, size_t n);
int memcmp(const void *s1, const void *s2, size_t n);
void *memcpy(void *dest, const void *src, size_t n);
void *memfrob(void *s, size_t n);
void *memmem(const void *needle, size_t needlelen,
const void *haystack, size_t haystacklen);
void *memmove(void *dest, const void *src, size_t n);
void *memset(void *s, int c, size_t n);
```

DESCRIPTION

The byte string functions perform operations on strings that are not `NULL` terminated. See the individual man pages for descriptions of each function.

htonl, htons, ntohl, ntohs

`htonl, htons, ntohl, ntohs`—Convert values between host and network byte order

SYNOPSIS

```
#include <netinet/in.h>
unsigned long int htonl(unsigned long int hostlong);
unsigned short int htons(unsigned short int hostshort);
```

```
unsigned long int ntohl(unsigned long int netlong);
unsigned short int ntohs(unsigned short int netshort);
```

DESCRIPTION

The `htonl()` function converts the long integer `hostlong` from host byte order to network byte order.

The `htons()` function converts the short integer `hostshort` from host byte order to network byte order.

The `ntohl()` function converts the long integer `netlong` from network byte order to host byte order.

The `ntohs()` function converts the short integer `netshort` from network byte order to host byte order.

On the i80x86, the host byte order is least significant byte first, whereas the network byte order, as used on the Internet, is most significant byte first.

CONFORMS TO

BSD 4.3

GNU, 9 April 1993

catgets

`catgets`—Gets message from a message catalog

SYNOPSIS

```
#include <features.h>
#include <nl_types.h>
char *catgets(nl_catd catalog, int set_number, int
message_number, char *message);
```

DESCRIPTION

`catgets()` reads the message `message_number`, in set `set_number`, from the message catalog identified by `catalog`. (`catalog` is a catalog descriptor returned from an earlier call to `catopen(3)`.) The fourth argument `message` points to a default message string that will be returned by `catgets()` if the identified message catalog is not currently open or is damaged. The message text is contained in an internal buffer area and should be copied by the application if it is to be saved or modified. The return string is always terminated with a null byte.

RETURN VALUES

On success, `catgets()` returns a pointer to an internal buffer area containing the null-terminated message string. `catgets()` returns a pointer to message if it fails because the message catalog specified by `catalog` is not currently open. Otherwise, `catgets()` returns a pointer to an empty string if the message catalog is available but does not contain the specified message.

NOTES

These functions are only available in `libc.so.4.4.4c` and above.

SEE ALSO

`catopen(3)`, `setlocale(3)`

29 November 1993

catopen, catclose

`catopen, catclose`—Open/close a message catalog

SYNOPSIS

```
#include <features.h>
#include <nl_types.h>
nl_catd catopen(char *name, int flag);
void catclose(nl_catd catalog);
```

DESCRIPTION

`catopen()` opens a message catalog and returns a catalog descriptor. `name` specifies the name of the message catalog to be opened. If `name` specifies an absolute path (that is, contains a `/`), `name` specifies a pathname for the message catalog. Otherwise, the environment variable `NLSPATH` is used, with `name` substituted for `%N` (see `locale(5)`). If `NLSPATH` does not exist in the environment, or if a message catalog cannot be opened in any of the paths specified by `NLSPATH`, the following paths are searched in order:

```
/etc/locale/LC_MESSAGES
/usr/lib/locale/LC_MESSAGES
/usr/lib/locale/name/LC_MESSAGES
```

In all cases, `LC_MESSAGES` stands for the current setting of the `LC_MESSAGES` category of locale from a previous call to `setlocale()` and defaults to the `C` locale. In the last search path, `name` refers to the catalog name.

The `flag` argument to `catopen` is used to indicate the type of loading desired. This should be either `MCLoadBySet` or `MCLoadAll`. The former value indicates that only the required set from the catalog is loaded into memory when needed, whereas the latter causes the initial call to `catopen()` to load the entire catalog into memory.

`catclose()` closes the message catalog identified by `catalog`. It invalidates any subsequent references to the message catalog defined by `catalog`.

RETURN VALUES

`catopen()` returns a message catalog descriptor of type `nl_catd` on success. On failure, it returns `-1`.

`catclose()` returns `0` on success, or `-1` on failure.

NOTES

These functions are only available in `libc.so.4.4.4c` and above. In the case of Linux, the catalog descriptor `n1_catd` is actually an area of memory assigned by `mmap()` and not a file descriptor, thus allowing catalogs to be shared.

clientlib

`clientlib`—NNTP `clientlib` part of InterNetNews library

SYNOPSIS

```
extern FILE *ser_rd_fp;
extern FILE *ser_wr_fp;
extern char ser_line[];
char * getserverbyfile(file);
char *file; int server_init(host);
char *host;
int handle_server_response(response, host);
int reponse;
char *host;
void put_server(text);
char *text;
int get_server(buff, buffsize);
char *buff;
int buffsize;
void close_server();
```

DESCRIPTION

The routines described in this manual page are part of the InterNetNews library, `libinn(3)`. They are replacements for the `clientlib` part of the NNTP distribution, and are intended to be used in building programs such as `nnn`.

`getserverbyfile` calls `GetConfigValue` to get the name of the local NNTP server. It returns a pointer to static space. The `file` parameter is ignored.

`server_init` opens a connect to the NNTP server at the specified `host`. It returns the server's response code or `-1` on error. If a connection was made, `ser_rd_fp` and `ser_wr_fp` can be used to read from and write to the server, respectively, and `ser_line` will contain the server's response. `ser_line` can also be used in other routines.

`handle_server_response` decodes the response, which comes from the server on `host`. If the client is authorized, it returns `0`. A client that is only allowed to read is authorized, but `handle_server_response` will print a message on the standard output. If the client is not authorized to talk to the server, a message is printed, and the routine returns `-1`.

`put_server` sends the text in `buff` to the server, adding the necessary NNTP line terminators and flushing the I/O buffer.

`get_server` reads a line of text from the server into `buff`, reading at most `buffsize` characters. Any trailing `\r\n` terminators are stripped off. `get_server` returns `-1` on error.

`close_server` sends a quit command to the server and closes the connection.

clock

`clock`—Determine processor time

SYNOPSIS

```
#include <time.h>
clock_t clock(void);
```

DESCRIPTION

The `clock()` function returns an approximation of processor time used by the program.

RETURN VALUE

The value returned is the CPU time used so far as a `clock_t`; to get the number of seconds used, divide by `CLOCKS_PER_SEC`.

CONFORMS TO

ANSI C

BUGS

The C standard allows for arbitrary values at the start of the program; take the difference between the value returned from a call to `clock()` at the start of the program and the value returned at the end for maximum portability.

The `times()` function call returns more information.

SEE ALSO

[times\(2\)](#)

GNU, 21 April 1993

closedir

`closedir`—Close a directory

SYNOPSIS

```
#include <sys/types.h>
#include <dirent.h>
int closedir(DIR *dir);
```

DESCRIPTION

The `closedir()` function closes the directory stream associated with `dir`. The directory stream descriptor `dir` is not available after this call.

RETURN VALUE

The `closedir()` function returns `0` on success or `-1` on failure.

ERRORS

EBADF Invalid directory stream descriptor `dir`.

CONFORMS TO

SVID 3, POSIX, BSD 4.3

SEE ALSO

confstr

`confstr`—Get configuration-dependent string variables

SYNOPSIS

```
#define __USE_POSIX_2
#include <unistd.h>
size_t confstr(int name, char *buf, size_t len);
```

DESCRIPTION

`confstr()` gets the value of configuration-dependent string variables.

The `name` argument is the system variable to be queried. The following variables are supported:

CS_PATH A value for the `PATH` variable that indicates where all the POSIX.2 standard utilities can be found.

If `buf` is not `NULL`, and `len` is not `0`, `confstr()` copies the value of the string to `buf` truncated to `len-1` characters if necessary, with a null character as termination. This can be detected by comparing the return value of `confstr()` against `len`.

If `len` is `0` and `buf` is `NULL`, `confstr()` just returns the value in Return Value.

RETURN VALUE

If `name` does not correspond to a valid configuration variable, `confstr()` returns `0`.

EXAMPLES

The following code fragment determines the path where you can find the POSIX.2 system utilities:

```
char *pathbuf; size_t n;
n = confstr(_CS_PATH, NULL, (size_t)0);
if ((pathbuf = malloc(n)) == NULL) abort();
confstr(_CS_PATH, pathbuf, n);
```

ERRORS

If the value of `name` is invalid, `errno` is set to `EINVAL`.

CONFORMS TO

Proposed POSIX.2

BUGS

POSIX.2 is not yet an approved standard; the information in this man page is subject to change.

copysign

`copysign`—Copies the sign of a number

SYNOPSIS

```
#include <math.h>
double copysign(double x, double y);
```

DESCRIPTION

The `copysign()` function returns a value whose absolute value matches `x`, but whose sign matches that of `y`.

CONFORMS TO

BSD 4.3

GNU, 6 June 1993

COS

`cos`—Cosine function

SYNOPSIS

```
#include <math.h>
double cos(double x);
```

DESCRIPTION

The `cos()` function returns the cosine of `x`, where `x` is given in radians.

RETURN VALUE

The `cos()` function returns a value between -1 and 1 .

crypt

crypt—Password and data encryption

SYNOPSIS

```
#include <unistd.h>
char *crypt(const char *key, const char *salt);
```

DESCRIPTION

`crypt` is the password-encryption function. It is based on the Data Encryption Standard algorithm, with variations intended (among other things) to discourage the use of hardware implementations of a key search.

`key` is a user's typed password.

`sal t` is a two-character string chosen from the set `[a-zA-Z0-9./]`. This string is used to perturb the algorithm in one of 4,096 different ways.

By taking the lowest seven bits of each character of the key, a 56-bit key is obtained. This 56-bit key is used to repeatedly encrypt a constant string (usually a string consisting of all `0s`). The returned value points to the encrypted password, a series of 13 printable ASCII characters (with the first two characters representing the salt itself). The return value points to static data whose content is overwritten by each call.

Warning: The key space consists of equal $7.2e16$ possible values. Exhaustive searches of this key space are possible using massively parallel computers. Software, such as `crack(1)`, is available to search the portion of this key space that is generally used by humans for passwords. Hence, password selection should, at minimum, avoid common words and names. Using a `passwd(1)` program that checks for crackable passwords during the selection process is recommended.

The DES algorithm itself has a few quirks that make using the `crypt(3)` interface a very poor choice for anything other than password authentication. If you are planning to use the `crypt(3)` interface for a cryptography project, don't do it; get a good book on encryption and one of the widely available DES libraries instead.

CONFORMS TO

SVID, X/OPEN, BSD 4.3

3 September 1994

ctermid

ctermid—Gets controlling terminal name

SYNOPSIS

```
#include <stdio.h>
char *ctermid(char *s);
```

DESCRIPTION

ctermid() returns a string that is the pathname for the current controlling terminal for this process. If *s* is NULL, a static buffer is used; otherwise, *s* points to a buffer used to hold the terminal pathname. The symbolic constant `L_ctermid` is the maximum number of characters in the returned pathname.

RETURN VALUE

This function returns the pointer to the pathname.

CONFORMS TO

POSIX.1

BUGS

The path returned might not uniquely identify the controlling terminal; it might, for example, be `/dev/tty`.

It is not assured that the program can open the terminal.

SEE ALSO

ttyname(3)

GNU, 6 April 1993

asctime, ctime, gmtime, localtime, mktime

asctime, ctime, gmtime, localtime, mktime—Transform binary date and time to ASCII

SYNOPSIS

```
#include <time.h>
char *asctime(const struct tm *timeptr);
char *ctime(const time_t *timep);
struct tm *gmtime(const time_t *timep);
struct tm *localtime(const time_t *timep);
time_t mktime(struct tm *timeptr);
extern char *tzname[2];
long int timezone;
extern int daylight;
```

DESCRIPTION

The `ctime()`, `gmtime()`, and `localtime()` functions all take an argument of data type `time_t`, which represents calendar time. When interpreted as an absolute time value, it represents the number of seconds elapsed since 00:00:00 on January 1, 1970, Coordinated Universal Time (UTC).

The `asctime()` and `mktime()` functions both take an argument representing broken-down time, which is a binary representation separated into year, month, day, and so on. Broken-down time is stored in the structure `tm`, which is defined in `<time.h>` as follows:

```
struct tm
{
int tm_sec; /* seconds */
int tm_min; /* minutes */
int tm_hour; /* hours */
int tm_mday; /* day of the month */
int tm_mon; /* month */
int tm_year; /* year */
int tm_wday; /* day of the week */
int tm_yday; /* day in the year */
int tm_isdst; /* daylight saving time */
};
```

The members of the `tm` structure are

<code>tm_sec</code>	The number of seconds after the minute, normally in the range 0 to 59, but can be up to 61 to allow for leap seconds.
<code>tm_min</code>	The number of minutes after the hour, in the range 0 to 59.
<code>tm_hour</code>	The number of hours past midnight, in the range 0 to 23.
<code>tm_mday</code>	The day of the month, in the range 1 to 31.
<code>tm_mon</code>	The number of months since January, in the range 0 to 11.
<code>tm_year</code>	The number of years since 1900.
<code>tm_wday</code>	The number of days since Sunday, in the range 0 to 6.
<code>tm_yday</code>	The number of days since January 1, in the range 0 to 365.
<code>tm_isdst</code>	A flag that indicates whether daylight savings time is in effect at the time described. The value is positive if daylight saving time is in effect, 0 if it is not, and negative if the information is not available.

The `ctime()` function converts the calendar time `timep` into a string of the form

```
"Wed Jun 30 21:49:08 1993\n"
```

The abbreviations for the days of the week are Sun, Mon, Tue, Wed, Thu, Fri, and Sat. The abbreviations for the months are Jan, Feb, Mar, Apr, May, Jun, Jul, Aug, Sep, Oct, Nov, and Dec. The return value points to a statically allocated string that might be overwritten by subsequent calls to any of the date and time functions. The function also sets the external variable `tzname` with information about the current time zone.

The `gmtime()` function converts the calendar time `timep` to broken-down time representation, expressed in Coordinated Universal Time (UTC).

The `localtime()` function converts the calendar time `timep` to broken-time representation, expressed relative to the user's specified time zone. The function sets the external variables `tzname` with information about the current time zone, `timezone` with the difference between Coordinated Universal Time and local standard time in seconds, and `daylight` to a nonzero value if standard U.S. daylight saving time rules apply.

The `asctime()` function converts the broken-down time value `timeptr` into a string with the same format as `ctime()`. The return value points to a statically allocated string that might be overwritten by subsequent calls to any of the date and time functions.

The `mktime()` function converts a broken-down time structure, expressed as local time, to calendar time representation. The function ignores the specified contents of the structure members `tm_wday` and `tm_yday` and recomputes them from the other information in the broken-down time structure. Calling `mktime()` also sets the external variable `tzname` with information about the current time zone. If the specified broken-down time cannot be represented as calendar time, `mktime()` returns a value of `(time_t)(-1)` and does not alter the `tm_wday` and `tm_yday` members of the broken-down time structure.

drand48, erand48, lrand48, nrand48, mrand48, jrand48, srand48, seed48, lcong48

drand48, erand48, lrand48, nrand48, mrand48, jrand48, srand48, seed48, lcong48—Generate uniformly distributed pseudo-random numbers

SYNOPSIS

```
#include <stdlib.h>
double drand48(void);
double erand48(unsigned short int xsubi [3]);
long int lrand48(void);
long int nrand48(unsigned short int xsubi [3]);
long int mrand48(void);
long int jrand48(unsigned short int xsubi [3]);
void srand48(long int seedval);
unsigned short int * seed48(unsigned short int seed16v [3]);
void lcong48(unsigned short int param[7]);
```

DESCRIPTION

These functions generate pseudo-random numbers using the linear congruential algorithm and 48-bit integer arithmetic.

The `drand48()` and `erand48()` functions return non-negative double-precision floating-point values uniformly distributed between [0.0, 1.0].

The `lrand48()` and `nrand48()` functions return non-negative long integers uniformly distributed between 0 and 2^{31} .

The `mrand48()` and `jrand48()` functions return signed long integers uniformly distributed between -2^{31} and 2^{31} .

The `srand48()`, `seed48()`, and `lcong48()` functions are initialization functions, one of which should be called before using `drand48()`, `lrand48()`, or `mrand48()`. The functions `erand48()`, `nrand48()`, and `jrand48()` do not require an initialization function to be called first.

All the functions work by generating a sequence of 48-bit integers, X_i according to the linear congruential formula

$$X_{i+1} = (aX_i + c) \bmod m, \text{ where } i \geq 0$$

The parameter $m=2^{48}$; hence 48-bit integer arithmetic is performed. Unless `lcong48()` is called, a and c are given by

```
a = 0x5DEECE66D
c = 0xB
```

The value returned by any of the functions `drand48()`, `erand48()`, `lrand48()`, `nrand48()`, `mrand48()`, or `jrand48()` is computed by first generating the next 48-bit x_i in the sequence. Then the appropriate number of bits, according to the type of data item to be returned, is copied from the high-order bits of x_i and transformed into the returned value.

The functions `drand48()`, `lrand48()`, and `mrand48()` store the last 48-bit x_i generated in an internal buffer. The functions `erand48()`, `nrand48()`, and `jrand48()` require the calling program to provide storage for the successive x_i values in the array argument `xsubi`. The functions are initialized by placing the initial value of x_i into the array before calling the function for the first time.

The initializer function `srand48()` sets the high-order 32 bits of x_i to the argument `seedval`. The low-order 16 bits are set to the arbitrary value `0x330E`.

The initializer function `seed48()` sets the value of x_i to the 48-bit value specified in the array argument `seed16v`. The previous value of x_i is copied into an internal buffer and a pointer to this buffer is returned by `seed48()`.

The initialization function `lcong48()` allows the user to specify initial values for x_i , a and c . Array argument elements `param[0-2]` specify x_i , `param[3-5]` specify a , and `param[6]` specifies c . After `lcong48()` has been called, a subsequent call to either `srand48()` or `seed48()` will restore the standard values of a and c .

drem

`drem`—Floating-point remainder function

SYNOPSIS

```
#include <math.h>
double drem(double x, double y);
```

DESCRIPTION

The `drem()` function computes the remainder of dividing `x` by `y`. The return value is $x - n * y$, where n is the quotient of `x` divided by `y`, rounded to the nearest integer. If the quotient is $\frac{1}{2}$, it is rounded to the even number.

RETURN VALUE

The `drem()` function returns the remainder unless `y` is 0, in which case the function fails and `errno` is set.

ERRORS

EDOM The denominator `y` is 0.

CONFORMS TO

BSD 4.3

SEE ALSO

`fmod(3)`

ecvt, fcvt

`ecvt`, `fcvt`—Convert a floating-point number to a string

SYNOPSIS

```
#include <stdlib.h>
char *ecvt(double number, size_t ndigits, int*decpt, int*sign);
char *fcvt(double number, size_t ndigits, int*decpt, int*sign);
```

DESCRIPTION

The `ecvt()` function converts `number` to a NULL-terminated string of `ndigits` digits and returns a pointer to the string. The string itself does not contain a decimal point; however, the position of the decimal point relative to the start of the string is

stored in `decp`. A negative value for `decp` means that the decimal point is to the left of the start of the string. If the sign of `number` is negative, `sign` is set to a nonzero value; otherwise, it's set to 0.

The `fcvt()` function is identical to `ecvt()`, except that `ndigits` specifies the number of digits after the decimal point.

RETURN VALUE

Both the `ecvt()` and `fcvt()` functions return a pointer to a static string containing the ASCII representation of `number`. The static string is overwritten by each call to `ecvt()` or `fcvt()`.

erf, erfc

`erf`, `erfc`—Error function and complementary error function

SYNOPSIS

```
#include <math.h>
double erf(double x);
double erfc (double x);
```

DESCRIPTION

The `erf()` function returns the error function of `x`, defined as

$$\text{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x \exp(-t^2) dt$$

The `erfc()` function returns the complementary error function of `x`—that is, $1.0 - \text{erf}(x)$.

execl, execlp, execl, exect, execv, execvp

`execl`, `execlp`, `execl`, `exect`, `execv`, `execvp`—Execute a file

SYNOPSIS

```
#include <unistd.h>
extern char **environ;
int execl(const char *path, const char *arg, ...);
int execlp(const char *file, const char *arg, ...);
int execl(const char *path, const char *arg, ...);
int execlp(const char *file, const char *arg, ...);
int execl(const char *path, const char *arg, ...);
int execl(const char *path, const char *arg, ..., char * const envp[]);
int exect(const char *path, char *const argv[]);
int execv(const char *path, char *const argv[]);
int execvp(const char *file, char *const argv[]);
```

DESCRIPTION

The `exec` family of functions replaces the current process image with a new process image. The functions described in this manual page are front ends for the function `execve(2)`. (See the manual page for `execve` for detailed information about the replacement of the current process.)

The initial argument for these functions is the pathname of a file that is to be executed.

The `const char *arg` and subsequent ellipses in the `execl`, `execlp`, and `execl` functions can be thought of as `arg0`, `arg1`, ..., `argn`. Together they describe a list of one or more pointers to null-terminated strings that represent the argument list available to the executed program. The first argument, by convention, should point to the file name associated with the file being executed. The list of arguments must be terminated by a `NULL` pointer.

The `exect`, `execv`, and `execvp` functions provide an array of pointers to null-terminated strings that represent the argument list available to the new program. The first argument, by convention, should point to the filename associated with the file being executed. The array of pointers must be terminated by a `NULL` pointer.

The `execl` and `exect` functions also specify the environment of the executed process by following the `NULL` pointer that terminates the list of arguments in the parameter list or the pointer to the `argv` array with an additional parameter. This additional parameter is an array of pointers to null-terminated strings and must be terminated by a `NULL` pointer. The other functions take the environment for the new process image from the external variable `environ` in the current process.

Some of these functions have special semantics.

The functions `execlp` and `execvp` will duplicate the actions of the shell in searching for an executable file if the specified filename does not contain a slash (`/`) character. The search path is the path specified in the environment by the `PATH` variable. If this variable isn't specified, the default path `/bin:/usr/bin:` is used (is this true for Linux?). In addition, certain errors are treated specially.

If permission is denied for a file (the attempted `execve` returned `EACCES`), these functions will continue searching the rest of the search path. If no other file is found, however, they will return with the global variable `errno` set to `EACCES`.

If the header of a file isn't recognized (the attempted `execve` returned `ENOEXEC`), these functions will execute the shell with the path of the file as its first argument. (If this attempt fails, no further searching is done.)

If the file is currently busy (the attempted `execve` returned `ETXTBUSY`), these functions will sleep for several seconds, periodically re-attempting to execute the file. (Is this true for Linux?)

The function `exect` executes a file with the program-tracing facilities enabled (see `ptrace(2)`).

RETURN VALUES

If any of the `exec` functions returns, an error will have occurred. The return value is `-1`, and the global variable `errno` will be set to indicate the error.

FILES

`/bin/sh`

ERRORS

`execl`, `execl`, `execlp`, and `execvp` may fail and set `errno` for any of the errors specified for the library functions `execve(2)` and `malloc(3)`.

`exect` and `execv` may fail and set `errno` for any of the errors specified for the library function `execve(2)`.

SEE ALSO

`sh(1)`, `execve(2)`, `fork(2)`, `trace(2)`, `environ(5)`, `ptrace(2)`

COMPATIBILITY

Historically, the default path for the `execlp` and `execvp` functions was `/bin:/usr/bin`. This was changed to place the current directory last to enhance system security.

The behavior of `execlp` and `execvp` when errors occur while attempting to execute the file is historic practice, but has not traditionally been documented and is not specified by the POSIX standard.

Traditionally, the functions `execlp` and `execvp` ignored all errors except for the ones described above and `ENOMEM` and `E2BIG`, upon which they returned. They now return if any error other than the ones described in the “Errors” section occurs.

STANDARDS

`execl`, `execv`, `execlp`, and `execvp` conform to IEEE Std1003.1-88 (POSIX.1).

BSD Man Page, 29 November 1993

errno

`errno`—Number of last error

SYNOPSIS

```
#include <errno.h>
extern int errno;
```

DESCRIPTION

The integer `errno` is set by system calls (and some library functions) to indicate what went wrong. Its value is significant only when the call returns an error (usually `-1`), and a library function that does succeed is allowed to change `errno`.

Sometimes, when `-1` is also a legal return value, you have to set `errno` to `0` before the call in order to detect possible errors.

POSIX lists the following symbolic error names:

<code>E2BIG</code>	Arg list too long
<code>EACCES</code>	Permission denied
<code>EAGAIN</code>	Resource temporarily unavailable
<code>EBADF</code>	Bad file descriptor
<code>EBUSY</code>	Resource busy
<code>ECHILD</code>	No child processes
<code>EDEADLK</code>	Resource deadlock avoided
<code>EDOM</code>	Domain error
<code>EEXIST</code>	File exists
<code>EFAULT</code>	Bad address
<code>EFBIG</code>	File too large
<code>EINTR</code>	Interrupted function call
<code>EINVAL</code>	Invalid argument
<code>EIO</code>	Input/output error
<code>EISDIR</code>	Is a directory
<code>EMFILE</code>	Too many open files
<code>EMLINK</code>	Too many links
<code>ENAMETOOLONG</code>	Filename too long
<code>ENFILE</code>	Too many open files in system
<code>ENODEV</code>	No such device
<code>ENOENT</code>	No such file or directory
<code>ENOEXEC</code>	Exec format error
<code>ENOLCK</code>	No locks available
<code>ENOMEM</code>	Not enough space

ENOSPC	No space left on device
ENOSYS	Function not implemented
ENOTDIR	Not a directory
ENOTEMPTY	Directory not empty
ENOTTY	Inappropriate I/O control operation
ENXIO	No such device or address
EPERM	Operation not permitted
EPIPE	Broken pipe
ERANGE	Result too large
EROFS	Read-only filesystem
ESPIPE	Invalid seek
ESRCH	No such process
EXDEV	Improper link

*21 July 1996***exit**

exit—Causes normal program termination

SYNOPSIS

```
#include <stdlib.h>
void exit(int status);
```

DESCRIPTION

The `exit()` function causes normal program termination, and the value of `status` is returned to the parent. All functions registered with `atexit()` and on `exit()` are called in the reverse order of their registration, and all open streams are flushed and closed.

RETURN VALUE

The `exit()` function does not return.

*GNU, 2 April 1993***exp, log, log10, pow**

exp, log, log10, pow—Exponential, logarithmic, and power functions

SYNOPSIS

```
#include <math.h>
double exp(double x);
```

```
double log(double x);
double log10(double x);
double pow(double x, double y);
```

DESCRIPTION

The `exp()` function returns the value of e (the base of natural logarithms) raised to the power of x .

The `log()` function returns the natural logarithm of x .

The `log10()` function returns the base-10 logarithm of x .

The `pow()` function returns the value of x raised to the power of y .

ERRORS

The `log()` and `log10()` functions can return the following errors:

EDOM	The argument x is negative.
ERANGE	The argument x is 0. The log of 0 is not defined.

The `pow()` function can return the following error:

EDOM	The argument x is negative and y is not an integral value. This would result in a complex number.

expm1, log1p

`expm1`, `log1p`—Exponential minus 1, logarithm of 1 plus argument

SYNOPSIS

```
#include <math.h>
double expm1 (double x);
double log1p (double x);
```

DESCRIPTION

`expm1(x)` returns a value equivalent to $\exp(x) - 1$. It is computed in a way that is accurate even if the value of x is near 0—a case where $\exp(x) - 1$ would be inaccurate due to subtraction of two numbers that are nearly equal.

`log1p(x)` returns a value equivalent to $\log(1 + x)$. It is computed in a way that is accurate even if the value of x is near 0.

fclose

`fclose`—Closes a stream

SYNOPSIS

```
#include <stdio.h>
int fclose(FILE *stream);
```

DESCRIPTION

The `fclose` function dissociates the named `stream` from its underlying file or set of functions. If the stream was being used for output, any buffered data is written first, using `fflush(3)`.

RETURN VALUES

Upon successful completion, `0` is returned. Otherwise, `EOF` is returned, and the global variable `errno` is set to indicate the error. In either case, no further access to the stream is possible.

ERRORS

EBAADF The argument `stream` is not an open stream.

The `fclose` function may also fail and set `errno` for any of the errors specified for the routines `close(2)` or `fflush(3)`.

SEE ALSO

`close(2)`, `fflush(3)`, `fopen(3)`, `setbuf(3)`

STANDARDS

The `fclose` function conforms to ANSI C3.159-1989 ("ANSI C").

BSD Man Page, 29 November 1993

clearerr, feof, ferror, fileno

`clearerr`, `feof`, `ferror`, `fileno`—Check and reset stream status

SYNOPSIS

```
#include <stdio.h>
void clearerr( FILE *stream);
int feof(FILE *stream);
int ferror(FILE *stream);
int fileno(FILE *stream);
```

DESCRIPTION

The function `clearerr` clears the end-of-file and error indicators for the stream pointed to by `stream`.

The function `feof` tests the end-of-file indicator for the stream pointed to by `stream`, returning nonzero if it is set. The end-of-file indicator can only be cleared by the function `clearerr`.

The function `ferror` tests the error indicator for the stream pointed to by `stream`, returning nonzero if it is set. The error indicator can only be reset by the `clearerr` function.

The function `fileno` examines the argument `stream` and returns its integer descriptor.

ERRORS

These functions should not fail and do not set the external variable `errno`.

SEE ALSO

`open(2)`, `stdio(3)`

STANDARDS

The functions `clearerr`, `feof`, and `ferror` conform to C3.159-1989 (“ANSI C”).

BSD Man Page, 29 November 1993

fflush, fpurge

`fflush`, `fpurge`—Flush a stream

SYNOPSIS

```
#include <stdio.h>
int fflush( FILE *stream);
int fpurge( FILE *stream);
```

DESCRIPTION

The function `fflush` forces a write of all buffered data for the given output or update stream via the stream’s underlying write function. The open status of the stream is unaffected.

If the stream argument is `NULL`, `fflush` flushes all open output streams. (Does this happen under Linux?)

The function `fpurge` erases any input or output buffered in the given stream. For output streams, this discards any unwritten output. For input streams, this discards any input read from the underlying object but not yet obtained via `getc(3)`; this includes any text pushed back via `ungetc`.

RETURN VALUES

Upon successful completion, `0` is returned. Otherwise, `EOF` is returned, and the global variable `errno` is set to indicate the error.

ERRORS

EBAADF Stream is not an open stream, or, in the case of `fflush`, not a stream open for writing.

The function `fflush` may also fail and set `errno` for any of the errors specified for the routine `write(2)`.

BUGS

Linux may not support `fpurge`.

SEE ALSO

`write(2)`, `fopen(3)`, `fclose(3)`, `setbuf(3)`

STANDARDS

The `fflush` function conforms to ANSI C3.159-1989 (“ANSI C”).

BSD Man Page, 29 November 1993

ffs

`ffs`—Finds first bit set in a word

SYNOPSIS

```
#include <string.h>
int ffs(int i);
```

DESCRIPTION

The `ffs()` function returns the position of the first bit set in the word `i`. The least significant bit is position 1, and the most significant position 32.

RETURN VALUE

The `ffs()` function returns the position of the first bit set, or `NULL` if no bits are set.

CONFORMS TO

BSD 4.3

GNU, 13 April 1993

fgetgrent

`fgetgrent`—Gets group file entry

SYNOPSIS

```
#include <grp.h>
#include <stdio.h>
#include <sys/types.h>
struct group *fgetgrent(FILE *stream);
```

DESCRIPTION

The `fgetgrent()` function returns a pointer to a structure containing the group information from the file `stream`. The first time it is called it returns the first entry; thereafter, it returns successive entries. The file `stream` must have the same format as `/etc/group`.

The group structure is defined in `<grp.h>` as follows:

```
struct group {
    char    *gr_name;        /* group name */
    char    *gr_passwd;     /* group password */
    gid_t   gr_gid;        /* group id */
    char    **gr_mem;       /* group members */
};
```

RETURN VALUE

The `fgetgrent()` function returns the group information structure, or `NULL` if there are no more entries or an error occurs.

ERRORS

`ENOMEM` Insufficient memory to allocate group information structure.

CONFORMS TO

SVID 3

fgetpwent

`fgetpwent`—Gets password file entry

SYNOPSIS

```
#include <pwd.h>
#include <stdio.h>
#include <sys/types.h>
struct passwd *fgetpwent(FILE *stream);
```

DESCRIPTION

The `fgetpwent()` function returns a pointer to a structure containing the broken-out fields of a line in the file `stream`. The first time it is called it returns the first entry; thereafter, it returns successive entries. The file `stream` must have the same format as `/etc/passwd`.

The `passwd` structure is defined in `<pwd.h>` as follows:

```
struct passwd {
    char    *pw_name;        /* username */
    char    *pw_passwd;     /* user password */
    uid_t   pw_uid;        /* user id */
    gid_t   pw_gid;        /* group id */
    char    *pw_gecos;     /* real name */
    char    *pw_dir;       /* home directory */
    char    *pw_shell;     /* shell program */
};
```

RETURN VALUE

The `fgetpwent()` function returns the `passwd` structure, or `NULL` if there are no more entries or an error occurs.

ERRORS

`ENOMEM` Insufficient memory to allocate `passwd` structure.

fnmatch

fnmatch—Matches filename or pathname

SYNOPSIS

```
#include <fnmatch.h>
int fnmatch(const char *pattern, const char *strings, int flags);
```

DESCRIPTION

fnmatch() checks the `strings` argument and checks whether it matches the `pattern` argument, which is a shell wildcard pattern.

The `flags` argument modifies the behavior; it is the bitwise OR of zero or more of the following flags:

FNM_NOESCAPE	If this flag is set, treat backslash as an ordinary character instead of as an escape character.
FNM_PATHNAME	If this flag is set, match a slash in <code>string</code> only with a slash in <code>pattern</code> and not, for example, with a <code>[] -</code> sequence containing a slash.
FNM_PERIOD	If this flag is set, a leading period in <code>string</code> has to be matched exactly by a period in <code>pattern</code> . A period is considered to be leading if it is the first character in <code>string</code> , or if both <code>FNM_PATHNAME</code> is set and the period immediately follows a slash.

RETURN VALUE

Zero if `string` matches `pattern`, `FNM_NOMATCH` if there is no match, or another value if there is an error.

CONFORMS TO

Proposed POSIX.2

BUGS

POSIX.2 is not yet an approved standard; the information in this man page is subject to change.

fopen, fdopen, freopen

fopen, fdopen, freopen—Stream open functions

SYNOPSIS

```
#include <stdio.h>
FILE *fopen(char *path, char *mode);
FILE *fdopen(int fildes, char *mode);
FILE *freopen(char *path, char *mode, FILE *stream);
```

DESCRIPTION

The `fopen` function opens the file whose name is the string pointed to by `path` and associates a stream with it.

The argument `mode` points to a string beginning with one of the following sequences (additional characters may follow these sequences):

r	Open text file for reading. The stream is positioned at the beginning of the file.
r+	Open for reading and writing. The stream is positioned at the beginning of the file.

w	Truncate file to zero length or create a text file for writing. The stream is positioned at the beginning of the file.
w+	Open for reading and writing. The file is created if it does not exist; otherwise it is truncated. The stream is positioned at the beginning of the file.
a	Open for writing. The file is created if it does not exist. The stream is positioned at the end of the file.
a+	Open for reading and writing. The file is created if it does not exist. The stream is positioned at the end of the file.

The `mode` string can also include the letter `b` either as a third character or as a character between the characters in any of the two-character strings described previously. This is strictly for compatibility with ANSI C3.159-1989 (ANSI C) and has no effect; the `b` is ignored.

Any created files will have mode `S_IRUSR|S_IWUSR|S_IRGRP|S_IWGRP|S_IROTH|S_IWOTH` (0666), as modified by the process's `umask` value. (See `umask(2)`.)

Reads and writes may be intermixed on read/write streams in any order. Note that ANSI C requires that a file positioning function intervene between output and input, unless an input operation encounters end-of-file. (If this condition is not met, then a read is allowed to return the result of writes other than the most recent.) Therefore it is good practice (and indeed sometimes necessary under Linux) to put an `fseek` or `fgetpos` operation between write and read operations on such a stream. This operation may be an apparent no-op (as in `fseek(..., 0L, SEEK_CUR)`) called for its synchronizing side effect.

The `fdopen` function associates a stream with the existing file descriptor, `filides`. The `mode` of the stream must be compatible with the mode of the file descriptor. The file descriptor is not duplicated.

The `freopen` function opens the file whose name is the string pointed to by `path` and associates the stream pointed to by `stream` with it. The original stream (if it exists) is closed. The `mode` argument is used just as in the `fopen` function. The primary use of the `freopen` function is to change the file associated with a standard text stream (`stderr`, `stdin`, or `stdout`).

RETURN VALUES

On successful completion, `fopen`, `fdopen`, and `freopen` return a `FILE` pointer. Otherwise, `NULL` is returned, and the global variable `errno` is set to indicate the error.

ERRORS

`EINVAL` The mode provided to `fopen`, `fdopen`, or `freopen` was invalid.

The `fopen`, `fdopen`, and `freopen` functions may also fail and set `errno` for any of the errors specified for the routine `malloc(3)`.

The `fopen` function may also fail and set `errno` for any of the errors specified for the routine `open(2)`.

The `fdopen` function may also fail and set `errno` for any of the errors specified for the routine `fcntl(2)`.

The `freopen` function may also fail and set `errno` for any of the errors specified for the routines `open(2)`, `fclose(3)` and `fflush(3)`.

SEE ALSO

`open(2)`, `fclose(3)`

STANDARDS

The `fopen` and `freopen` functions conform to ANSI C3.159-1989 (ANSI C). The `fdopen` function conforms to IEEE Std1003.1-1988 (POSIX.1).

BSD Man Page, 13 December 1995

fpathconf, pathconf

fpathconf, pathconf—Get configuration values for files

SYNOPSIS

```
#include <unistd.h>
long fpathconf(int filedes, int name);
long pathconf(char *path, int name);
```

DESCRIPTION

`fpathconf()` gets a value for the configuration option `name` for the open file descriptor `filedes`.

`pathconf()` gets a value for configuration option `name` for the filename `path`.

The corresponding macros defined in `<unistd.h>` are the minimum values; if an application wants to take advantage of values that may change, a call to `fpathconf()` or `pathconf()` can be made, which may yield more liberal results.

Setting `name` equal to one of the following constants returns the following configuration options:

<code>_PC_LINK_MAX</code>	Returns the maximum number of links to the file. If <code>filedes</code> or <code>path</code> refers to a directory, the value applies to the whole directory. The corresponding macro is <code>_POSIX_LINK_MAX</code> .
<code>_PC_MAX_CANON</code>	Returns the maximum length of a formatted input line, where <code>filedes</code> or <code>path</code> must refer to a terminal. The corresponding macro is <code>_POSIX_MAX_CANON</code> .
<code>_PC_MAX_INPUT</code>	Returns the maximum length of an input line, where <code>filedes</code> or <code>path</code> must refer to a terminal. The corresponding macro is <code>_POSIX_MAX_INPUT</code> .
<code>_PC_NAME_MAX</code>	Returns the maximum length of a filename in the directory <code>path</code> or <code>filedes</code> the process is allowed to create. The corresponding macro is <code>_POSIX_NAME_MAX</code> .
<code>_PC_PATH_MAX</code>	Returns the maximum length of a relative pathname when <code>path</code> or <code>filedes</code> is the current working directory. The corresponding macro is <code>_POSIX_PATH_MAX</code> .
<code>_PC_PIPE_BUF</code>	Returns the size of the pipe buffer, where <code>filedes</code> must refer to a pipe or FIFO, and <code>path</code> must refer to a FIFO. The corresponding macro is <code>_POSIX_PIPE_BUF</code> .
<code>_PC_CHOWN_RESTRICTED</code>	Returns nonzero if the <code>chown(2)</code> call may not be used on this file. If <code>filedes</code> or <code>path</code> refers to a directory, this applies to all files in that directory. The corresponding macro is <code>_POSIX_CHOWN_RESTRICTED</code> .
<code>_PC_NO_TRUNC</code>	Returns nonzero if accessing filenames longer than <code>_POSIX_NAME_MAX</code> generates an error. The corresponding macro is <code>_POSIX_NO_TRUNC</code> .
<code>_PC_VDISABLE</code>	Returns nonzero if special character processing can be disabled, where <code>filedes</code> or <code>path</code> must refer to a terminal.

RETURN VALUE

The limit is returned, if one exists. If the system does not have a limit for the requested resource, `-1` is returned, and `errno` is unchanged. If there is an error, `-1` is returned, and `errno` is set to reflect the nature of the error.

CONFORMS TO

POSIX.1. Files with name lengths longer than the value returned for `name` equal to `_PC_NAME_MAX` may exist in the given directory.

Some returned values may be huge; they are not suitable for allocating memory.

fread, fwrite

`fread`, `fwrite`—Binary stream input/output

SYNOPSIS

```
#include <stdio.h>
size_t fread(void *ptr, size_t size, size_t nmem, FILE*stream);
size_t fwrite(void *ptr, size_t size, size_t nmem, FILE*stream);
```

DESCRIPTION

The function `fread` reads `nmem` elements of data, each `size` bytes long, from the stream pointed to by `stream`, storing them at the location given by `ptr`.

The function `fwrite` writes `nmem` elements of data, each `size` bytes long, to the stream pointed to by `stream`, obtaining them from the location given by `ptr`.

RETURN VALUES

`fread` and `fwrite` return the number of items successfully read or written (that is, not the number of characters). If an error occurs, or the end-of-file is reached, the return value is a short item count (or 0).

`fread` does not distinguish between end-of-file and error, and callers must use `feof(3)` and `ferror(3)` to determine which occurred.

SEE ALSO

`feof(3)`, `ferror(3)`, `read(2)`, `write(2)`

STANDARDS

The functions `fread` and `fwrite` conform to ANSI C3.159-1989 ("ANSI C").

BSD Man Page, 17 May 1996

frexp

`frexp`—Converts floating-point number to fractional and integral components

SYNOPSIS

```
#include <math.h>
double frexp(double x, int *exp);
```

DESCRIPTION

The `frexp()` function is used to split the number `x` into a normalized fraction and an exponent that is stored in `exp`.

RETURN VALUE

The `frexp()` function returns the normalized fraction. If the argument `x` is not 0, the normalized fraction is `x` times a power of 2, and is always in the range $\frac{1}{2}$ (inclusive) to 1 (exclusive). If `x` is 0, the normalized fraction is 0, and 0 is stored in `exp`.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

`ldexp(3)`, `modf(3)`

GNU, 6 June 1993

fgetpos, fseek, fsetpos, ftell, rewind

`fgetpos`, `fseek`, `fsetpos`, `ftell`, `rewind`—Reposition a stream

SYNOPSIS

```
#include <stdio.h>
int fseek(FILE *stream, longo fset, int whence);
long ftell(FILE *stream);
void rewind(FILE *stream);
int fgetpos(FILE *stream, fpos_t *pos);
int fsetpos(FILE *stream, fpos_t *pos);
```

DESCRIPTION

The `fseek` function sets the file position indicator for the stream pointed to by `stream`. The new position, measured in bytes, is obtained by adding offset bytes to the position specified by `whence`. If `whence` is set to `SEEK_SET`, `SEEK_CUR`, or `SEEK_END`, the offset is relative to the start of the file, the current position indicator, or end-of-file, respectively. A successful call to the `fseek` function clears the end-of-file indicator for the stream and undoes any effects of the `ungetc(3)` function on the same stream.

The `ftell` function obtains the current value of the file position indicator for the stream pointed to by `stream`.

The `rewind` function sets the file position indicator for the stream pointed to by `stream` to the beginning of the file. It is equivalent to

```
(void)fseek(stream, 0L, SEEK_SET);
```

except that the error indicator for the stream is also cleared. (See `clearerr(3)`.)

The `fgetpos` and `fsetpos` functions are alternate interfaces equivalent to `ftell` and `fseek` (with `whence` set to `SEEK_SET`), setting and storing the current value of the file offset into or from the object referenced by `pos`. On some non-UNIX systems, an `fpos_t` object may be a complex object, and these routines might be the only way to portably reposition a text stream.

RETURN VALUES

The `rewind` function returns no value. Upon successful completion, `fgetpos`, `fseek`, and `fsetpos` return 0, and `ftell` returns the current offset. Otherwise, -1 is returned, and the global variable `errno` is set to indicate the error.

ERRORS

EADF	The stream specified is not a seekable stream.
EINVAL	The <code>whence</code> argument to <code>fseek</code> was not <code>SEEK_SET</code> , <code>SEEK_END</code> , or <code>SEEK_CUR</code> .

The function `fgetpos`, `fseek`, `fsetpos`, and `ftell` might also fail and set `errno` for any of the errors specified for the routines `fflush(3)`, `fstat(2)`, `lseek(2)`, and `malloc(3)`.

SEE ALSO

`lseek(2)`

STANDARDS

The `fgetpos`, `fsetpos`, `fseek`, `ftell`, and `rewind` functions conform to ANSI C3.159-1989 (ANSI C).

BSD Man Page, 29 November 1993

ftime

`ftime`—Returns date and time

SYNOPSIS

```
#include <sys/timex.h>
int ftime(struct timex *tp);
```

DESCRIPTION

Return current date and time in `tp`, which is declared as follows:

```
struct timeb {
    time_t time;
    unsigned short millitm;
    short timezone;
    short dstflag;
};
```

RETURN VALUE

This function always returns 0.

NOTES

Under Linux, this function is implemented in a compatibility library instead of in the kernel.

CONFORMS TO

Version 7, BSD 4.3

Under BSD 4.3, this call is obsoleted by `gettimeofday(2)`.

SEE ALSO

`time(2)`

ftok

`ftok`—Converts a pathname and a project identifier to a System V IPC key

SYNOPSIS

```
#include <sys/types.h>
#include <sys/ipc.h>
key_t ftok (char *pathname, char proj);
```

DESCRIPTION

The function converts the pathname of an existing accessible file and a project identifier into a `key_t` type System V IPC key.

RETURN VALUE

On success, the return value will be the converted `key_t` value; otherwise it will be `-1`, with `errno` indicating the error as for the `stat(2)` system call.

BUGS

The generated `key_t` value is obtained by stating the disk file corresponding to `pathname` in order to get its `i`-node number and the minor device number of the filesystem on which the disk file resides, then by combining the 8-bit `proj` value along with the lower 16 bits of the inode number with the 8 bits of the minor device number. The algorithm does not guarantee a unique key value. In fact,

- Two different names linking to the same file produce the same key values.
- Using the lower 16 bits of the `i`-node number gives some chance (although usually small) to have the same key values for filenames referring to different inodes.
- Not discriminating among major device numbers gives some chance of collision (also usually small) for systems with multiple disk controllers.

Linux 0.99.13, 1 November 1993

ftw

`ftw`—File tree walk

SYNOPSIS

```
#include <ftw.h>
int ftw(const char *directory,
int(*funcptr)(const char *file, struct stat *sb, int flag), int depth);
```

DESCRIPTION

`ftw()` walks through the directory tree, starting from the indicated `directory`. For each found entry in the tree, it calls `funcptr` with the full pathname of the entry relative to `directory`, a pointer to the `stat(2)` structure for the entry and an `int` whose value will be one of the following:

<code>FTW_F</code>	Item is a normal file
<code>FTW_D</code>	Item is a directory
<code>FTW_NS</code>	The <code>stat</code> failed on the item
<code>FTW_DNR</code>	Item is a directory which can't be read

Warning: Anything other than directories, such as symbolic links, gets the `FTW_F` tag.

`ftw()` recursively calls itself for traversing found directories. To avoid using up all a program's file descriptors, `depth` specifies the number of simultaneous open directories. When the depth is exceeded, `ftw()` will become slower because directories have to be closed and reopened.

To stop the tree walk, `funcptr` returns a nonzero value; this value will become the return value of `ftp()`. Otherwise, `ftw()` will continue until it has traversed the entire tree (in which case it will return 0), or until it hits an error such as a `malloc(3)` failure, in which case it will return -1.

Because `ftp()` uses dynamic data structures, the only safe way to exit a tree walk is to return a nonzero value. To handle interrupts, for example, mark that the interrupt occurred and return a nonzero value—don't use `longjmp(3)` unless the program is going to terminate.

gcvt

`gcvt`—Converts a floating-point number to a string

SYNOPSIS

```
#include <stdlib.h>
char *gcvt(double number, size_t ndigit, char *buf);
```

DESCRIPTION

The `gcvt()` function converts `number` to a minimal-length, NULL-terminated ASCII string and stores the result in `buf`. It produces `ndigit` significant digits in either `printf()` F format or E format.

RETURN VALUE

The `gcvt()` function returns the address of the string pointed to by `buf`.

getcwd, get_current_dir_name, getwd

`getcwd`, `get_current_dir_name`, `getwd`—Get current working directory

SYNOPSIS

```
#include <unistd.h>
char *getcwd(char *buf, size_t size);
char *get_current_working_dir_name(void);
char *getwd(char *buf);
```

DESCRIPTION

The `getcwd()` function copies the absolute pathname of the current working directory to the array pointed to by `buf`, which is of length `size`.

If the current absolute pathname would require a buffer longer than `size` elements, `NULL` is returned, and `errno` is set to `ERANGE`; an application should check for this error, and allocate a larger buffer if necessary.

As an extension to the POSIX.1 standard, `getcwd()` allocates the buffer dynamically using `malloc()` if `buf` is `NULL` on call. In this case, the allocated buffer has the length `size` unless `size` is less than 0, when `buf` is allocated as large as necessary. It is possible (and, indeed, advisable) to free the buffers if they have been obtained this way.

`get_current_dir_name`, which is only prototyped if `__USE_GNU` is defined, will `malloc(3)` an array big enough to hold the current directory name. If the environment variable `PWD` is set, and its value is correct, that value will be returned.

`getwd`, which is only prototyped if `__USE_BSD` is defined, will not `malloc(3)` any memory. The `buf` argument should be a pointer to an array at least `PATH_MAX` bytes long. `getwd` returns only the first `PATH_MAX` bytes of the actual pathname.

RETURN VALUE

`NULL` on failure (for example, if the current directory is not readable), with `errno` set accordingly, and `buf` on success.

CONFORMS TO

POSIX.1

SEE ALSO

`chdir(2)`, `free(3)`, `malloc(3)`.

getdirentries

`getdirentries`—Gets directory entries in a filesystem-independent format

SYNOPSIS

```
#define __USE_BSD or #define __USE_MISC
#include <dirent.h>
ssize_t getdirentries(int fd, char *buf, size_t nbytes, off_t *basep);
```

DESCRIPTION

This function reads directory entries from the directory specified by `fd` into `buf`. At most, `nbytes` are read. Reading starts at offset `*basep`, and `*basep` is updated with the new position after reading.

RETURN VALUE

`getdirentries` returns the number of bytes read, or 0 when at the end of the directory. If an error occurs, -1 is returned, and `errno` is set appropriately.

ERRORS

See the Linux library source code for details.

SEE ALSO

getenv

`getenv`—Gets an environment variable

SYNOPSIS

```
#include <stdlib.h>
char *getenv(const char *name);
```

DESCRIPTION

The `getenv()` function searches the environment list for a string that matches the string pointed to by `name`. The strings are of the form `name=value`.

RETURN VALUE

The `getenv()` function returns a pointer to the value in the environment, or `NULL` if there is no match.

CONFORMS TO

GNU, 3 April 1993

getgrent, setgrent, endgrent

`getgrent`, `setgrent`, `endgrent`—Get group file entry

SYNOPSIS

```
#include <grp.h>
#include <sys/types.h>
struct group *getgrent(void);
void setgrent(void);
void endgrent(void);
```

DESCRIPTION

The `getgrent()` function returns a pointer to a structure containing the group information from `/etc/group`. The first time it is called it returns the first entry; thereafter, it returns successive entries.

The `setgrent()` function rewinds the file pointer to the beginning of the `/etc/group` file.

The `endgrent()` function closes the `/etc/group` file.

The group structure is defined in `<grp.h>` as follows:

```
struct group {
    char    *gr_name;    /* group name */
    char    *gr_passwd;  /* group password */
    gid_t   gr_gid;     /* group id */
    char    **gr_mem;   /* group members */
};
```

RETURN VALUE

The `getgrent()` function returns the group information structure, or `NULL` if there are no more entries or an error occurs.

ERRORS

`ENOMEM` Insufficient memory to allocate group information structure.

FILES

`/etc/group` group database file

CONFORMS TO

getgrnam, getgrgid—Get group file entry

SYNOPSIS

```
#include <grp.h>
#include <sys/types.h>
struct group *getgrnam(const char *name);
struct group *getgrgid(gid_t gid);
```

DESCRIPTION

The `getgrnam()` function returns a pointer to a structure containing the group information from `/etc/group` for the entry that matches the group name `name`.

The `getgrgid()` function returns a pointer to a structure containing the group information from `/etc/group` for the entry that matches the group id `gid`.

The group structure is defined in `<grp.h>` as follows:

```
struct group {
    char    *gr_name;    /* group name */
    char    *gr_passwd;  /* group password */
```

```

    gid_t   gr_gid;      /* group id */
    char    **gr_mem;    /* group members */
};

```

RETURN VALUE

The `getgrnam()` and `getgrgid()` functions return the group information structure, or `NULL` if the matching entry is not found or an error occurs.

ERRORS

`ENOMEM` Insufficient memory to allocate group information structure.

FILES

`/etc/group` group database file

getlogin, cuserid

`getlogin, cuserid`—Get username

SYNOPSIS

```

#include <unistd.h>
char * getlogin ( void );
#include <stdio.h>
char * cuserid ( char *string );

```

DESCRIPTION

`getlogin` returns a pointer to a string containing the name of the user logged in on the controlling terminal of the process, or a null pointer if this information cannot be determined. The string is statically allocated and might be overwritten on subsequent calls to this function or to `cuserid`.

`cuserid` returns a pointer to a string containing a username associated with the effective user ID of the process. If `string` is not a null pointer, it should be an array that can hold at least `L_cuserid` characters; the string is returned in this array. Otherwise, a pointer to a string in a static area is returned. This string is statically allocated and might be overwritten on subsequent calls to this function or to `getlogin`.

The macro `L_cuserid` is an integer constant that indicates how long an array you might need to store a username. `L_cuserid` is declared in `stdio.h`.

These functions let your program positively identify the user who is running (`cuserid`) or the user who logged in this session (`getlogin`). (These can differ when `setuid` programs are involved.) The user cannot do anything to fool these functions.

For most purposes, it is more useful to use the environment variable `LOGNAME` to find out who the user is. This is more flexible precisely because the user can set `LOGNAME` arbitrarily.

ERRORS

`ENOMEM` Insufficient memory to allocate `passwd` structure.

FILES

The `/etc/passwd` password database file `/etc/utmp` (or `/var/adm/utmp`, or wherever your `utmp` file lives these days—the proper location depends on your `libc` version)

CONFORMS TO

POSIX.1. System V has a `cuserid` function that uses the real user ID rather than the effective user ID. The `cuserid` function was included in the 1988 version of POSIX, but was removed from the 1990 version.

BUGS

Unfortunately, it is often rather easy to fool `getlogin()`. Sometimes it does not work at all, because some program messed up the `utmp` file. Often, it gives only the first eight characters of the login name. The user currently logged in on the controlling tty of your program need not be the user who started it.

Nobody knows precisely what `cuserid()` does; so

- Avoid it in portable programs
- Avoid it altogether
- Use `getpwuid` (`geteuid()`) instead, if that is what you meant.

Simply, *do not use* `cuserid()`.

SEE ALSO

`geteuid(2)`, `getuid(2)`

Linux 1.2.13, 3 September 1995

getmntent, setmntent, addmntent, endmntent, hasmntopt

`getmntent`, `setmntent`, `addmntent`, `endmntent`, `hasmntopt`—Get filesystem descriptor file entry

SYNOPSIS

```
#include <stdio.h>
#include <mntent.h>
FILE *setmntent(const char *filep, const char *type);
struct mntent *getmntent(FILE *filep);
int addmntent(FILE *filep, const struct mntent *mnt);
int endmntent(FILE *filep);
char *hasmntopt(const struct mntent *mnt, const char *opt);
```

DESCRIPTION

These routines are used to access the filesystem description file `/etc/fstab` and the mounted filesystem description file `/etc/mstab`.

The `setmntent()` function opens the filesystem description file `filep` and returns a file pointer that can be used by `getmntent()`. The argument `type` is the type of access required and can take the same values as the `mode` argument of `fopen(3)`.

The `getmntent()` function reads the next line from the filesystem description file `filep` and returns a pointer to a structure containing the broken-out fields from a line in the file. The pointer points to a static area of memory that is overwritten by subsequent calls to `getmntent()`.

The `addmntent()` function adds the `mntent` structure `mnt` to the end of the open file `filep`.

The `endmntent()` function closes the filesystem description file `filep`.

The `hasmntopt()` function scans the `mnt_opts` field of the `mntent` structure `mnt` for a substring that matches `opt`. (See `<mntent.h>` for valid mount options.)

The `mntent` structure is defined in `<mntent.h>` as follows:

```
struct mntent {
    char    *mnt_fsname;    /* name of mounted filesystem */
    char    *mnt_dir;      /* filesystem path prefix */
    char    *mnt_type;     /* mount type (see mntent.h) */
    char    *mnt_opts;     /* mount options (see mntent.h) */
    int     mnt_freq;     /* dump frequency in days */
    int     mnt_passno;    /* pass number on parallel fsck */
};
```

RETURN VALUE

The `getmntent()` function returns a pointer to the `mntent` structure or `NULL` on failure.

The `addmntent()` function returns `0` on success and `1` on failure.

The `endmntent()` functions always returns `1`.

The `hasmntopt()` function returns the address of the substring if a match is found, and `NULL` otherwise.

FILES

`/etc/fstab` filesystem description file

`/etc/mtab` mounted filesystem description file

CONFORMS TO

BSD 4.3

getnetent, getnetbyaddr, getnetbyname, setnetent, endnetent

`getnetent`, `getnetbyaddr`, `getnetbyname`, `setnetent`, `endnetent`—Get network entry

SYNTAX

```
#include <netdb.h>
struct netent *getnetent()
struct netent *getnetbyname(name)
char *name;
struct netent *getnetbyaddr(net, type)
long net; int type;
void setnetent(stayopen)
int stayopen;
void endnetent()
```

DESCRIPTION

The `getnetent`, `getnetbyname`, and `getnetbyaddr` subroutines each return a pointer to an object with the following structure, containing the broken-out fields of a line in the network database, `/etc/networks`:

```
struct netent {
    char    *n_name;      /* official name of net */
    char    **n_aliases; /* alias list */
    int     n_addrtype;   /* net number type */
    long    n_net;        /* net number */
};
```

The members of this structure are

<code>n_name</code>	The official name of the network.
<code>n_aliases</code>	A zero-terminated list of alternate names for the network.
<code>n_addrtype</code>	The type of the network number returned: <code>AF_INET</code> .
<code>n_net</code>	The network number. Network numbers are returned in machine byte order.

If the `stayopen` flag on a `setnetent` subroutine is `NULL`, the network database is opened. Otherwise the `setnetent` has the effect of rewinding the network database. The `endnetent` may be called to close the network database when processing is complete.

The `getnetent` subroutine simply reads the next line whereas `getnetbyname` and `getnetbyaddr` search until a matching name or net number is found (or until EOF is encountered). The type must be `AF_INET`. The `getnetent` subroutine keeps a pointer in the database, allowing successive calls to be used to search the entire file.

A call to `setnetent` must be made before a `while` loop using `getnetent` to perform initialization, and an `endnetent` must be used after the loop. Both `getnetbyname` and `getnetbyaddr` make calls to `setnetent` and `endnetent`.

FILES

`/etc/networks`

DIAGNOSTICS

Null pointer (`0`) returned on EOF or error.

SEE ALSO

`networks(5)`, RFC 1101

HISTORY

The `getnetent()`, `getnetbyaddr()`, `getnetbyname()`, `setnetent()`, and `endnetent()` functions appeared in 4.2BSD.

BUGS

The data space used by these functions is static; if future use requires the data, it should be copied before any subsequent calls to these functions overwrite it. Only Internet network numbers are currently understood. Expecting network numbers to fit in no more than 32 bits is probably naive.

getopt

`getopt`—Parses command-line options

SYNOPSIS

```
#include <unistd.h>
int getopt(int argc, char * const argv[],
           const char *optstring);
extern char *optarg;
extern int optind, opterr, optopt;
#include <getopt.h>
int getopt_long(int argc, char * const argv[],

               const char *optstring,
               const struct option *longopts, int *longindex);
int getopt_long_only(int argc, char * const argv[],

                    const char *optstring,
                    const struct option *longopts, int *longindex);
```

DESCRIPTION

The `getopt()` function parses the command-line arguments. Its arguments `argc` and `argv` are the argument count and array as passed to the `main()` function on program invocation. An element of `argv` that starts with `-` (and is not exactly `-` or `--`) is an option element. The characters of this element (aside from the initial `-`) are option characters. If `getopt()` is called repeatedly, it returns successively each of the option characters from each of the option elements.

If `getopt()` finds another option character, it returns that character, updating the external variable `optind` and a static variable `nextchar` so that the next call to `getopt()` can resume the scan with the following option character or `argv` element.

If there are no more option characters, `getopt()` returns EOF. Then `optind` is the index in `argv` of the first `argv` element that is not an option.

`optstring` is a string containing the legitimate option characters. If such a character is followed by a colon, the option requires an argument, so `getopt` places a pointer to the following text in the same `argv` element, or the text of the following `argv` element, in `optarg`. Two colons mean an option takes an optional `arg`; if there is text in the current `argv` element, it is returned in `optarg`; otherwise, `optarg` is set to `0`.

By default, `getargs()` permutes the contents of `argv` as it scans, so that eventually all the non-options are at the end. Two other modes are also implemented. If the first character of `optstring` is `+` or the environment variable `POSIXLY_CORRECT` is set, option processing stops as soon as a non-option argument is encountered. If the first character of `optstring` is `-`, each non-option `argv` element is handled as if it were the argument of an option with character code 1. (This is used by programs that were written to expect options and other `argv` elements in any order and that care about the ordering of the two.) The special argument `-` forces an end of option-scanning regardless of the scanning mode.

If `getopt()` does not recognize an option character, it prints an error message to `stderr`, stores the character in `optopt`, and returns `?`. The calling program may prevent the error message by setting `opterr` to `0`.

The `getopt_long()` function works like `getopt()`, except that it also accepts long options, started out by two dashes. Long option names may be abbreviated if the abbreviation is unique or is an exact match for some defined option. A long option may take a parameter, of the form `--arg=param` or `--arg param`.

`longopts` is a pointer to the first element of an array of `struct option` declared in `<getopt.h>`:

```
as struct option {
    const char *name;
    int has_arg;
    int *flag;
    int val;
};
```

The meanings of the different fields are

<code>name</code>	The name of the long option.
<code>has_arg</code>	<code>no_argument</code> (or <code>0</code>) if the option does not take an argument, <code>required_argument</code> (or <code>1</code>) if the option requires an argument, or <code>optional_argument</code> (or <code>2</code>) if the option takes an optional argument.
<code>flag</code>	Specifies how results are returned for a long option. If <code>flag</code> is <code>NULL</code> , <code>getopt_long()</code> returns <code>val</code> . (For example, the calling program might set <code>val</code> to the equivalent short option character.) Otherwise, <code>getopt_long()</code> returns <code>0</code> , and <code>flag</code> points to a variable that is set to <code>val</code> if the option is found, but left unchanged if the option is not found.
<code>val</code>	The value to return or to load into the variable pointed to by <code>flag</code> .

The last element of the array has to be filled with zeroes.

If `longindex` is not `NULL`, it points to a variable that is set to the index of the long option relative to `longopts`.

`getopt_long_only()` is like `getopt_long()`, but `-` as well as `--` can indicate a long option. If an option that starts with `-` (not `--`) doesn't match a long option but does match a short option, it is parsed as a short option instead.

RETURN VALUE

The `getopt()` function returns the option character if the option was found successfully, `:` if there was a missing parameter for one of the options, `?` for an unknown option character, or `EOF` for the end of the option list.

`getopt_long()` and `getopt_long_only()` also return the option character when a short option is recognized. For a long option, they return `val` if `flag` is `NULL`, and `0` otherwise. Error and `EOF` returns are the same as for `getopt()`, plus `?` for an ambiguous match or an extraneous parameter.

ENVIRONMENT VARIABLES

`POSIXLY_CORRECT` If this is set, option processing stops as soon as a non-option argument is encountered.

EXAMPLE

The following example program, from the source code, illustrates the use of `getopt_long()` with most of its features:

```
#include <stdio.h>
int
main (argc, argv)
    int argc;
    char **argv;
{
    int c;
    int digit_optind = 0;
    while (1)
    {
        int this_option_optind = optind ? optind : 1;
        int option_index = 0;
        static struct option long_options[] =
        {
            {"add", 1, 0, 0},
            {"append", 0, 0, 0},
            {"delete", 1, 0, 0},
            {"verbose", 0, 0, 0},
            {"create", 1, 0, 'c'},
            {"file", 1, 0, 0g, f0, 0, 0, 0}
        };
        c = getopt_long (argc, argv, "abc:d:012",
            long_options, &option_index);
        if (c == -1)
            break;
        switch(c)
        {
            case 0:
                printf ("option %s", long_options[option_index].name);
                if (optarg)
                    printf (" with arg %s", optarg);
                printf ("\n");
                break;
            case '0':
            case '1':
            case '2':
                if (digit_optind != 0 && digit_optind != this_option_optind)
                    printf ("digits occur in two different argv-elements.\n");
                digit_optind = this_option_optind;
                printf ("option %c\n", c);
                break;
            case 'a':
                printf ("option a\n");
                break;
            case 'b':
```

```

    printf ("option b\n");
    break;
case 'c':
    printf ("option c with value '%s'\n", optarg);
    break;
case 'd':
    printf ("option d with value '%s' \n", optarg);
    break;
case '?':
    break;
default:
    printf ("?? getopt returned character code 0%o ??\n", c);
}
}
if (optind < argc)
{
    printf ("non-option ARGV-elements: ");
    while (optind < argc)
        printf ("%s ", argv[optind++]);
    printf ("\n");
}
exit (0);
}

```

BUGS

This man page is confusing.

CONFORMS TO

`getopt()`: POSIX.1, provided the environment variable `POSIXLY_CORRECT` is set. Otherwise, the elements of `argv` aren't really `const`, because they get permuted. They're set `const` in the prototype to be compatible with other systems.

GNU, 30 August 1995

getpass

`getpass`—Gets a password

SYNOPSIS

```

#include <pwd.h>
#include <unistd.h>
char *getpass( const char * prompt );

```

DESCRIPTION

The `getpass` function displays a prompt to, and reads in, a password from, `/dev/tty`. If this file is not accessible, `getpass` displays the prompt on the standard error output and reads from the standard input.

The password may be up to `_PASSWORD_LEN` (currently 128) characters in length. Any additional characters and the terminating newline character are discarded. (This might be different in Linux.)

`getpass` turns off character echoing while reading the password.

RETURN VALUES

`getpass` returns a pointer to the null-terminated password.

FILES

/dev/tty

SEE ALSO

crypt(3)

HISTORY

A `getpass` function appeared in Version 7 AT&T UNIX.

BUGS

The `getpass` function leaves its result in an internal static object and returns a pointer to that object. Subsequent calls to `getpass` will modify the same object.

The calling process should zero the password as soon as possible to avoid leaving the cleartext password visible in the process's address space.

BSD Man Page 29 November 1993

getprotoent, getprotobyname, getprotobynumber, setprotoent, endprotoent

getprotoent, getprotobyname, getprotobynumber, setprotoent, endprotoent—Get protocol entry

SYNOPSIS

```
#include <netdb.h>
struct protoent *getprotoent(void);
struct protoent *getprotobyname(const char *name);
struct protoent *getprotobynumber(int proto);
void setprotoent(int stayopen);
void endprotoent(void);
```

DESCRIPTION

The `getprotoent()` function reads the next line from the file `/etc/protocols` and returns a structure `protoent` containing the broken-out fields from the line. The `/etc/protocols` file is opened if necessary.

The `getprotobyname()` function returns a `protoent` structure for the line from `/etc/protocols` that matches the protocol name `name`.

The `getprotobynumber()` function returns a `protoent` structure for the line that matches the protocol number `number`.

The `setprotoent()` function opens and rewinds the `/etc/protocols` file. If `stayopen` is true (1), the file will not be closed between calls to `getprotobyname()` or `getprotobynumber()`.

The `endprotoent()` function closes `/etc/protocols`.

The `protoent` structure is defined in `<netdb.h>` as follows:

```
struct protoent {
    char    *p_name;        /* official protocol name */
    char    **p_aliases;    /* alias list */
    int     p_proto;        /* protocol number */
}
```

The members of the `protoent` structure are

<code>p_name</code>	The official name of the protocol.
<code>p_aliases</code>	A zero-terminated list of alternative names for the protocol.
<code>p_proto</code>	The protocol number.

RETURN VALUE

The `getprotoent()`, `getprotobyname()`, and `getprotobynumber()` functions return the `protoent` structure, or a `NULL` pointer if an error occurs or the end of the file is reached.

FILES

`/etc/protocols` protocol database file

getpw

`getpw`—Reconstructs password line entry

SYNOPSIS

```
#include <pwd.h>
#include <sys/types.h>
int getpw(uid_t uid, char *buf);
```

DESCRIPTION

The `getpw()` function reconstructs the password line entry for the given user UID `uid` in the buffer `buf`. The returned buffer contains a line of format

```
name:passwd:uid:gid:gecos:dir:shell
```

The `passwd` structure is defined in `<pwd.h>` as follows:

```
struct passwd {
    char    *pw_name;      /*username*/
    char    *pw_passwd;   /* user password */
    uid_t   pw_uid;       /* user id */
    gid_t   pw_gid;       /* group id */
    char    *pw_gecos;    /* real name */
    char    *pw_dir;      /* home directory */
    char    *pw_shell;    /* shell program */
};
```

RETURN VALUE

The `getpw()` function returns `0` on success, or `-1` if an error occurs.

ERRORS

`ENOMEM` Insufficient memory to allocate `passwd` structure.

FILES

`/etc/passwd` Password database file

SEE ALSO

getpwent, setpwent, endpwent

getpwent, setpwent, endpwent—get password file entry

SYNOPSIS

```
#include <pwd.h>
#include <sys/types.h>
struct passwd *getpwent(void);
void setpwent(void);
void endpwent(void);
```

DESCRIPTION

The `getpwent()` function returns a pointer to a structure containing the broken-out fields of a line from `/etc/passwd`. The first time it is called it returns the first entry; thereafter, it returns successive entries.

The `setpwent()` function rewinds the file pointer to the beginning of the `/etc/passwd` file.

The `endpwent()` function closes the `/etc/passwd` file.

The `passwd` structure is defined in `<pwd.h>` as follows:

```
struct passwd {
    char    *pw_name;      /*username*/
    char    *pw_passwd;   /* user password */
    uid_t   pw_uid;       /* user id */
    gid_t   pw_gid;       /* group id */
    char    *pw_gecos;    /* real name */
    char    *pw_dir;      /* home directory */
    char    *pw_shell;    /* shell program */
};
```

RETURN VALUE

The `getpwent()` function returns the `passwd` structure, or `NULL` if there are no more entries or an error occurs.

ERRORS

`ENOMEM` Insufficient memory to allocate `passwd` structure.

FILES

getpwnam, getpwuid

getpwnam, getpwuid—Get password file entry

SYNOPSIS

```
#include <pwd.h>
#include <sys/types.h>
struct passwd *getpwnam(const char * name);
struct passwd *getpwuid(uid_t uid);
```

DESCRIPTION

The `getpwnam()` function returns a pointer to a structure containing the broken out fields of a line from `/etc/passwd` for the entry that matches the username `name`.

The `getpwuid()` function returns a pointer to a structure containing the broken-out fields of a line from `/etc/passwd` for the entry that matches the user UID `uid`.

The `passwd` structure is defined in `<pwd.h>` as follows:

```
struct passwd {
    char    *pw_name;      /*username*/
    char    *pw_passwd;   /* user password */
    uid_t   pw_uid;       /* user id */
    gid_t   pw_gid;       /* group id */
    char    *pw_gecos;    /* real name */
    char    *pw_dir;      /* home directory */
    char    *pw_shell;    /* shell program */
};
```

RETURN VALUE

The `getpwnam()` and `getpwuid()` functions return the `passwd` structure, or `NULL` if the matching entry is not found or an error occurs.

ERRORS

`ENOMEM` Insufficient memory to allocate `passwd` structure.

fgetc, fgets, getc, getchar, gets, ungetc

fgetc, fgets, getc, getchar, gets, ungetc—Input of characters and strings

SYNOPSIS

```
#include <stdio.h>
int fgetc(FILE *stream);
char *fgets(char *s, int size, FILE *stream);
```

```
int getc(FILE *stream);
int getchar(void);
char *gets(char *s);
int ungetc(int c, FILE *stream);
```

DESCRIPTION

`fgetc()` reads the next character from `stream` and returns it as an unsigned char cast to an int, or EOF on end of file or error.

`getc()` is equivalent to `fgetc()` except that it can be implemented as a macro that evaluates `stream` more than once.

`getchar()` is equivalent to `getc(stdin)`.

`gets()` reads a line from `stdin` into the buffer pointed to by `s` until either a terminating newline or EOF, which it replaces with `\0`. No check for buffer overrun is performed (see the following “Bus” section).

`fgets()` reads in at most one less than `n` characters from `stream` and stores them into the buffer pointed to by `s`. Reading stops after an EOF or a newline. If a newline is read, it is stored into the buffer. `\0` is stored after the last character in the buffer.

`ungetc()` pushes `c` back to `stream`, cast to unsigned char, where it is available for subsequent read operations. Pushed-back characters will be returned in reverse order; only one pushback is guaranteed.

Calls to the functions described here can be mixed with each other and with calls to other input functions from the `stdio` library for the same input stream.

RETURN VALUES

`fgetc()`, `getc()`, and `getchar()` return the character read as an unsigned char cast to an int, or EOF on end of file or error.

`gets()` and `fgets()` return `s` on success, and `NULL` on error or when end of file occurs while no characters have been read.

`ungetc()` returns `c` on success, or EOF on error.

CONFORMS TO

ANSI—C, POSIX.1

BUGS

Because it is impossible to tell without knowing the data in advance how many characters `gets()` will read, and because `gets()` will continue to store characters past the end of the buffer, it is extremely dangerous to use. It has been used to break computer security. Use `fgets()` instead.

It is not advisable to mix calls to input functions from the `stdio` library with low-level calls to `read()` for the file descriptor associated with the input stream; the results will be undefined and very probably not what you want.

getservent, getservbyname, getservbyport, setservent, endservent

getservent, getservbyname, getservbyport, setservent, endservent—Get service entry

SYNOPSIS

```
#include <netdb.h>
struct servent *getservent(void);
struct servent *getservbyname(const char *name, const char *proto);
struct servent *getservbyport(int port, const char *proto);
```

```
void setservent(int stayopen);
void endservent(void);
```

DESCRIPTION

The `getservent()` function reads the next line from the file `/etc/services` and returns a structure, `servent`, containing the broken out fields from the line. The `/etc/services` file is opened if necessary.

The `getservbyname()` function returns a `servent` structure for the line from `/etc/services` that matches the service name using protocol `proto`.

The `getservbyport()` function returns a `servent` structure for the line that matches the port `port` given in network byte order using protocol `proto`.

The `setservent()` function opens and rewinds the `/etc/services` file. If `stayopen` is true (1), the file will not be closed between calls to `getservbyname()` and `getservbyport()`.

The `endservent()` function closes `/etc/services`.

The `servent` structure is defined in `<netdb.h>` as follows:

```
struct servent {
char *s_name; /* official service name */
char **s_aliases; /* alias list */
int s_port; /* port number */
char *s_proto; /* protocol to use */
}
```

The members of the `servent` structure are:

<code>s_name</code>	The official name of the service.
<code>s_aliases</code>	A zero-terminated list of alternative names for the service.
<code>s_port</code>	The port number for the service, given in network byte order.
<code>s_proto</code>	The name of the protocol to use with this service.

RETURN VALUE

The `getservent()`, `getservbyname()`, and `getservbyport()` functions return the `servent` structure, or a `NULL` pointer if an error occurs or the end of the file is reached.

FILES

`/etc/services` Services database file

getusershell, setusershell, endusershell

`getusershell`, `setusershell`, `endusershell`—Get legal user shells

SYNOPSIS

```
#include <unistd.h>
char *getusershell(void);
```

```
void setusershell(void);
void endusershell(void);
```

DESCRIPTION

The `getusershell()` function returns the next line from the file `/etc/shells`, opening the file if necessary. The line should contain the pathname of a valid user shell. If `/etc/shells` does not exist or is unreadable, `getusershell()` behaves as if `/bin/sh` and `/bin/csh` were listed in the file.

The `setusershell()` function rewinds `/etc/shells`.

The `endusershell()` function closes `/etc/shells`.

RETURN VALUE

The `getusershell()` function returns a NULL pointer on end of file.

FILES

`/etc/shells`

CONFORMS TO

BSD 4.3

SEE ALSO

`shells(5)`

BSD, 4 July 1993

getutent, getutid, getutline, pututline, setutent, endutent, utmpname

`getutent, getutid, getutline, pututline, setutent, endutent, utmpname`—Access utmp file entries

SYNOPSIS

```
#include <utmp.h>
struct utmp *getutent(void);
struct utmp *getutid(struct utmp *ut);
struct utmp *getutline(struct utmp *ut);
void pututline(struct utmp *ut);
void setutent(void);
void endutent(void);
void utmpname(const char *file);
```

DESCRIPTION

`utmpname()` sets the name of the utmp-format file for the other utmp functions to access. If `utmpname()` is not used to set the filename before the other functions are used, they assume `PATH_UTMP`, as defined in `<paths.h>`.

`setutent()` rewinds the file pointer to the beginning of the utmp file. It is generally a good idea to call it before any of the other functions.

`endutent()` closes the utmp file. It should be called when the user code is done accessing the file with the other functions.

`getutent()` reads a line from the current file position in the utmp file. It returns a pointer to a structure containing the fields of the line.

`getutid()` searches forward from the current file position in the utmp file based on `ut`. If `ut->ut_type` is `RUN_LVL`, `BOOT_TIME`, `NEW_TIME`, or `OLD_TIME`, `getutid()` will find the first entry whose `ut_type` field matches `ut->ut_type`. If `ut->ut_type` is

INIT_PROCESS, LOGIN_PROCESS, USER_PROCESS, or DEAD_PROCESS, `getutid()` will find the first entry whose `ut_id` field matches `ut->ut_id`.

`getutline()` searches forward from the current file position in the `utmp` file. It scans entries whose `ut_type` is `USER_PROCESS` or `LOGIN_PROCESS` and returns the first one whose `ut_line` field matches `ut->ut_line`.

`pututline()` writes the `utmp` structure `ut` into the `utmp` file. It uses `getutid()` to search for the proper place in the file to insert the new entry. If it cannot find an appropriate slot for `ut`, `pututline()` will append the new entry to the end of the file.

RETURN VALUE

`getutent()`, `getutid()`, and `getutline()` return a pointer to a struct `utmp`, which is defined in `<utmp.h>`.

FILES

Linux libc 5.0.0, 22 March 1995

getw, putw

`getw`, `putw`—Input and output of words (ints)

SYNOPSIS

```
#include <stdio.h>
int getw(FILE *stream);
int putw(int w, FILE*stream);
```

DESCRIPTION

`getw` reads a word (that is, an `int`) from `stream`. It's provided for compatibility with SVID. I recommend you use `fread(3)` instead. `putw` writes the word `w` (that is, an `int`) to `stream`. It is provided for compatibility with SVID, but I recommend you use `fwrite(3)` instead.

RETURN VALUES

Normally, `getw` returns the word read, and `putw` returns the word written. On error, they return `EOF`.

BUGS

The value returned on error is also a legitimate data value. `ferror(3)` can be used to distinguish between the two cases.

CONFORMS TO

SVID

GNU, 16 September 1995

glob, globfree

glob, globfree—Find pathnames matching a pattern; free memory from glob()

SYNOPSIS

```
#include <glob.h>
int glob(const char *pattern, int flags,
int errfunc(const char * epath, int eerrno),
glob_t *pglob);
void globfree(glob_t *pglob);
```

DESCRIPTION

The `glob()` function searches for all the pathnames matching `pattern` according to the rules used by the shell (see `glob(7)`). No tilde expansion or parameter substitution is done.

The `globfree()` function frees the dynamically allocated storage from an earlier call to `glob()`.

The results of a `glob()` call are stored in the structure pointed to by `pglob`, which is a `glob_t` that is declared in `<glob.h>` as

```
typedef struct
{
    int gl_pathc;          /* Count of paths matched so far */
    char **gl_pathv;      /* List of matched pathnames. */
    int gl_offs;          /* Slots to reserve in 'gl_pathv'. */
    int gl_flags;         /* Flags for globbing */
} glob_t;
```

Results are stored in dynamically allocated storage.

The parameter `flags` is made up of bitwise OR of zero or more the following symbolic constants, which modify the behavior of `glob()`:

GLOB_ERR	Return on read error (because a directory does not have read permission, for example).
GLOB_MARK	Append a slash to each path which corresponds to a directory.
GLOB_NOSORT	Don't sort the returned pathnames (they are by default).
GLOB_DOOFS	<code>pglob->gl_offs</code> slots will be reserved at the beginning of the list of strings in <code>pglob->pathv</code> .
GLOB_NOCHECK	If no pattern matches, return the original pattern.
GLOB_APPEND	Append to the results of a previous call. Do not set this flag on the first invocation of <code>glob()</code> .
GLOB_NOESCAPE	Meta characters cannot be quoted by backslashes.
GLOB_PERIOD	A leading period can be matched by meta characters.

If `errfunc` is not `NULL`, it will be called in case of an error with the arguments `epath`, a pointer to the path that failed, and `eerrno`, the value of `errno` as returned from one of the calls to `opendir()`, `readdir()`, or `stat()`. If `errfunc` returns nonzero, or if `GLOB_ERR` is set, `glob()` will terminate after the call to `errfunc`.

Upon successful return, `pglob->gl_pathc` contains the number of matched pathnames and `pglob->gl_pathv` a pointer to the list of matched pathnames. The first pointer after the last pathname is `NULL`.

It is possible to call `glob()` several times. In that case, the `GLOB_APPEND` flag has to be set in `flags` on the second and later invocations.

RETURN VALUES

On successful completion, `glob()` returns 0. Other possible returns are

GLOB_NOSPACE	For running out of memory,
GLOB_ABEND	For a read error, and
GLOB_NOMATCH	For no found matches.

EXAMPLES

One example of use is the following code, which simulates typing in the shell:

```
ls -l *.c ../*.c

glob_t globbuf;
globbuf.gl_offs = 2;
glob("*.c", GLOB_DOOFS, NULL, &globbuf);
glob("../*.c", GLOB_DOOFS | GLOB_APPEND, NULL, &globbuf);
globbuf.gl_pathv[0] = "ls";
globbuf.gl_pathv[1] = "-l";
execvp("ls", &globbuf.gl_pathv[0]);
```

CONFORMS TO

Proposed POSIX.2

BUGS

The `glob()` function may fail due to failure of underlying function calls, such as `malloc()` or `opendir()`. These will store their error code in `errno`.

POSIX.2 is not yet an approved standard; the information in this man page is subject to change.

SEE ALSO

hosts_access, hosts_ctl

`hosts_access`, `hosts_ctl`—Access-control library functions

SYNOPSIS

```
#include "log_tcp.h"
extern int allow_severity;
extern int deny_severity;
int hosts_access(daemon, client)
char *daemon;
struct client_info *client;
int hosts_ctl(daemon, client_name, client_addr, client_user)
char *daemon;
char *client_name;
char *client_addr;
char *client_user;
```

DESCRIPTION

The routines described in this document are part of the `libwrap.a` library. They implement a pattern-based access-control language with optional shell commands that are executed when a pattern fires.

In all cases, the `daemon` argument should specify a daemon process name (`argv[0]` value). The client host address should be a valid address, or `FROM_UNKNOWN` if the address lookup failed. The client hostname and username should be empty strings if no information is available, `FROM_UNKNOWN` if the lookup failed, or an actual hostname or username.

`hosts_access()` consults the access-control tables described in the `hosts_access(5)` manual page. `hosts_access()` returns 0 if access should be denied.

`hosts_ctl()` is a wrapper around the `hosts_access()` routine with a perhaps more convenient interface (although it does not pass on enough information to support automated remote username lookups). `hosts_ctl()` returns 0 if access should be denied.

The `allow_severity` and `deny_severity` variables determine how accepted and rejected requests can be logged. They must be provided by the caller and can be modified by rules in the access-control tables.

DIAGNOSTICS

Problems are reported via the `syslog` daemon.

SEE ALSO

`hosts_access(5)` (format of the access control tables), `hosts_options(5)`, optional extensions to the base language

FILES

`/etc/hosts.access`, `/etc/hosts.deny` access-control tables

BUGS

The functions described here do not make copies of their string-valued arguments. Beware of data from functions that overwrite their results on each call.

`hosts_access()` uses the `strtok()` library function. This may interfere with other code that relies on `strtok()`.

hcreate, hdestroy, hsearch

`hcreate`, `hdestroy`, `hsearch`—Hash table management

SYNOPSIS

```
#include <search.h>
ENTRY *hsearch(ENTRY item, ACTION action);
int hcreate(unsigned nel);
void hdestroy(void);
```

DESCRIPTION

These three functions allow the user to create a hash table that associates a key with any data.

First, the table must be created with the function `hcreate()`. `nel` is an estimate of the number of entries in the table.

`hcreate()` may adjust this value upward to improve the performance of the resulting hash table. The GNU implementation of `hsearch()` will also enlarge the table if it gets nearly full. `malloc(3)` is used to allocate space for the table.

The corresponding function `hdestroy()` frees the memory occupied by the hash table so that a new table can be constructed.

`item` is of type `ENTRY`, which is a typedef defined in `<search.h>` and includes these elements:

```
typedef struct entry
{
    char *key;
    char *data;
} ENTRY;
```

`key` points to the zero-terminated ASCII string that is the search key. `data` points to the data associated with that key. (A pointer to a type other than character should be cast to pointer-to-character.) `hsearch()` searches the hash table for an item with the same key as `item`, and if successful returns a pointer to it. `action` determines what `hsearch()` does after an unsuccessful search. A value of `ENTER` instructs it to insert the new item, whereas a value of `FIND` means to return `NULL`.

RETURN VALUE

`hcreate()` returns NULL if the hash table cannot be successfully installed.

`hsearch()` returns NULL if `action` is `ENTER` and there is insufficient memory to expand the hash table, or if `action` is `FIND` and `item` cannot be found in the hash table.

CONFORMS TO

SVID, except that in SysV, the hash table cannot grow.

BUGS

The implementation can manage only one hash table at a time. Individual hash table entries can be added, but not deleted.

EXAMPLE

The following program inserts 24 items into a hash table and then prints some of them:

```
#include <stdio.h>
#include <search.h>
char *data[]={ "alpha", "bravo", "charley", "delta",
  "echo", "foxtrot", "golf", "hotel", "india", "juliette",
  "kilo", "lima", "mike", "november", "oscar", "papa",
  "quebec", "romeo", "sierra", "tango", "uniform",
  "victor", "whiskey", "x-ray", "yankee", "zulu"
};
int main()
{
  ENTRY e, *ep;
  int i;
  /* start with small table, and let it grow */
  hcreate(3);
  for (i = 0; i < 24; i++)
  {
    e.key = data[i];
    /* data is just an integer, instead of a pointer
       to something */
    e.data = (char *)i;
    ep = hsearch(e, ENTER);
    /* there should be no failures */
    if(ep == NULL) {fprintf(stderr, "entry failed\n"); exit(1);}
  }
  for (i = 22; i < 26; i++)
    /* print two entries from the table, and show that
       two are not in the table */
  {
    e.key = data[i];
    ep = hsearch(e, FIND);
    printf("%9.9s -> %9.9s:%d\n", e.key, ep?ep->key:"NULL",
      ep?(int)(ep->data):0);
  }
  return 0;
}
```

hypot

hypot—Euclidean distance function

SYNOPSIS

```
#include <math.h>
double hypot(double x, double y);
```

DESCRIPTION

The `hypot()` function returns the `sqrt(x*x+y*y)`. This is the length of the hypotenuse of a right-angle triangle with sides of length *x* and *y*, or the distance of the point (*x*, *y*) from the origin.

CONFORMS TO

SVID 3, BSD 4.3

SEE ALSO

`sqrt(3)`

index, rindex

index, rindex—Locate character in string

SYNOPSIS

```
#include <string.h>
char *index(const char *s,int c);
char *rindex(const char *s,int c);
```

DESCRIPTION

The `index()` function returns a pointer to the first occurrence of the character *c* in the string *s*.

The `rindex()` function returns a pointer to the last occurrence of the character *c* in the string *s*.

The terminating NULL character is considered to be a part of the strings.

RETURN VALUE

The `index()` and `rindex()` functions return a pointer to the matched character, or NULL if the character is not found.

inet_aton, inet_addr, inet_network, inet_ntoa, inet_makeaddr, inet_lnaof, inet_netof

`inet_aton`, `inet_addr`, `inet_network`, `inet_ntoa`, `inet_makeaddr`, `inet_lnaof`, `inet_netof`—Internet address—manipulation routines

SYNOPSIS

```
#include <sys/socket.h>
#include <netinet/in.h>
#include <arpa/inet.h>
int inet_aton(const char *cp, struct in_addr *inp);
unsigned long int inet_addr(const char *cp);
unsigned long int inet_network(const char *cp);
char *inet_ntoa(struct in_addr in);
struct in_addr inet_makeaddr(int net, int host);
unsigned long int inet_lnaof(struct in_addr in);
unsigned long int inet_netof(struct in_addr in);
```

DESCRIPTION

`inet_aton()` converts the Internet host address `cp` from the standard numbers-and-dots notation into binary data and stores it in the structure that `inp` points to. `inet_aton` returns nonzero if the address is valid, and 0 if it is not.

The `inet_addr()` function converts the Internet host address `cp` from numbers-and-dots notation into binary data in network byte order. If the input is invalid, -1 is returned. This is an obsolete interface to `inet_aton`; it is obsolete because -1 is a valid address (255.255.255.255), and `inet_aton` provides a cleaner way to indicate error return.

The `inet_network()` function extracts the network number in network byte order from the address `cp` in numbers-and-dots notation. If the input is invalid, -1 is returned.

The `inet_ntoa()` function converts the Internet host address given in network byte order to a string in standard numbers-and-dots notation. The string is returned in a statically allocated buffer, which subsequent calls will overwrite.

The `inet_makeaddr()` function makes an Internet host address in network byte order by combining the network number `net` with the local address `host` in network `net`, both in local host byte order.

The `inet_lnaof()` function returns the local host address part of the Internet address `in`. The local host address is returned in local host byte order.

The `inet_netof()` function returns the network number part of the Internet address `in`. The network number is returned in local host byte order.

The structure `in_addr` as used in `inet_ntoa()`, `inet_makeaddr()`, `inet_lnaof()`, and `inet_netof()` is defined in `netinet/in.h` as

```
struct in_addr {
    unsigned long int s_addr;
};
```

Note that on the i80x86 the host byte order is Least Significant Byte first, whereas the network byte order, as used on the Internet, is Most Significant Byte first.

infnan

`infnan`—Deals with infinite or not-a-number (NaN) result

SYNOPSIS

```
#include <math.h>
double infnan(int error);
```

DESCRIPTION

The `infnan()` function returns a suitable value for infinity and not-a-number (NaN) results. The value of `error` can be `ERANGE` to represent infinity, or anything else to represent NaN. `errno` is also set.

RETURN VALUE

If `error` is `ERANGE` (Infinity), `HUGE_VAL` is returned.

If `error` is `-ERANGE` (-Infinity), `-HUGE_VAL` is returned.

If `error` is anything else, NaN is returned.

ERRORS

`ERANGE` The value of `error` is positive or negative infinity.

`EDOM` The value of `error` is not-a-number (NaN).

CONFORMS TO

BSD 4.3

GNU, 2 June 1993

initgroups

`initgroups`—Initializes the supplementary group access list

SYNOPSIS

```
#include <grp.h>
#include <sys/types.h>
int initgroups(const char *user, gid_t group);
```

DESCRIPTION

The `initgroups()` function initializes the group access list by reading the group database `/etc/group` and using all groups of which `user` is a member. The additional `group` is also added to the list.

RETURN VALUE

The `initgroups()` function returns 0 on success, or -1 if an error occurs.

ERRORS

`EPERM` The calling process does not have sufficient privileges.

`ENOMEM` Insufficient memory to allocate group information structure.

FILES

`/etc/group` group database file

CONFORMS TO

SVID 3, BSD 4.3

inndcomm

inndcomm—INND communication part of InterNetNews library

SYNOPSIS

```
#include "inndcomm.h"
int ICCopen()
int ICCclose()
void ICCsettimeout(i)
int i;
int ICCcommand(cmd, argv, reply)
char cmd;
char *argv[];
char **reply;
int ICCcancel(msgid)
char *msgid;
int ICCreserve(why)
char *why;
int ICCpause(why)
char *why;
int ICCgo(why)
char *why;
extern char *ICCFailure;
```

DESCRIPTION

The routines described in this manual page are part of the InterNetNews library, `libinn(3)`. They are used to send commands to a running `innd(8)` daemon on the local host. The letters *ICC* stand for Innd Control Command.

`ICCopen` creates a UNIX-domain datagram socket and binds it to the server's control socket. It returns `-1` on failure or `0` on success. This routine must be called before any other routine.

`ICCclose` closes any descriptors that have been created by `ICCopen`. It returns `-1` on failure or `0` on success.

`ICCsettimeout` can be called before any of the following routines to determine how long the library should wait before giving up on getting the server's reply. This is done by setting and catching a `SIGALRM` signal(2). If the timeout is less than 0, no reply will be waited for. The `SC_SHUTDOWN`, `SC_XABORT`, and `SC_XEXEC` commands do not get a reply either. The default, which can be obtained by setting the timeout to 0, is to wait until the server replies.

`ICCcommand` sends the command `cmd` with parameters `argv` to the server. It returns `-1` on error. If the server replies, and `reply` is not `NULL`, it will be filled in with an allocated buffer that contains the full text of the server's reply. This buffer is a string in the form `<digits><space><text>` where `digits` is the text value of the recommended exit code; `0` indicates success. Replies longer than 4,000 bytes will be truncated. The possible values of `cmd` are defined in the `inndcomm.h` header file. The parameters for each command are described in `ctlinnd(8)`. This routine returns `-1` on communication failure; on success it returns the exit status sent by the server, which will never be negative.

`ICCcancel` sends a cancel message to the server. `msgid` is the message ID of the article that should be canceled. The return value is the same as for `ICCcommand`.

`ICCPause`, `ICCreserve`, and `ICCgo` send a pause, reserve, or go command to the server, respectively. If `ICCreserve` is used, the `why` value used in the `ICCPause` invocation must match; the value used in the `ICCgo` invocation must always match the one used in the `ICCPause` invocation. The return value for all three routines is the same as for `ICCcommand`.

If any of these routines fail, the `ICCFailure` variable will identify the system call that failed.

HISTORY

Written by Rich Salz (`rsalz@uunet.uu.net`) for InterNetNews.

insque, remque

insque, remque—Insert/Remove an item from a queue

SYNOPSIS

```
#include <stdlib.h>
void insque(struct qelem * elem, struct qelem * prev);
void remque(struct qelem * elem);
```

DESCRIPTION

`insque()` and `remque()` are functions for manipulating queues made from doubly linked lists. Each element in this list is of type `struct qelem`.

The `qelem` structure is defined as

```
struct qelem {
    struct qelem *q_forw;
    struct qelem *q_back;
    char q_data[1];
};
```

`insque()` inserts the element pointed to by `elem` immediately after the element pointed to by `prev`, which must *not* be `NULL`.

`remque()` removes the element pointed to by `elem` from the doubly linked list.

CONFORMS TO

SVR4

BUGS

The `q_data` field is sometimes defined to be of type `char *`, and under Solaris 2.x, it doesn't appear to exist at all.

The location of the prototypes for these functions differs among several versions of UNIX. Some systems place them in `<search.h>`, others in `<string.h>`. Linux places them in `<stdlib.h>` because that seems to make the most sense.

Some versions of UNIX (such as HP-UX 10.x) do not define a `struct qelem` but rather have the arguments to `insque()` and `remque()` be of type `void *`.

GNU, 30 October 1996

isalnum, isalpha, isascii, isblank, iscntrl, isdigit, isgraph, islower, isprint, ispunct, isspace, isupper, isxdigit

isalnum, isalpha, isascii, isblank, iscntrl, isdigit, isgraph, islower, isprint, ispunct, isspace, isupper, isxdigit—Character classification routines

SYNOPSIS

```
#include <ctype.h>
int isalnum (int c);
int isalpha (int c);
int isascii (int c);
int isblank (int c);
int iscntrl (int c);
int isdigit (int c);
int isgraph (int c);
int islower (int c);
int isprint (int c);
int ispunct (int c);
```

```
int isspace (int c);
int isupper (int c);
int isxdigit (int c);
```

DESCRIPTION

These functions check whether `c`, which must have the value of an `unsigned char` or `EOF`, falls into a certain character class according to the current locale:

<code>isalnum()</code>	Checks for an alphanumeric character; it is equivalent to <code>(isalpha(c) isdigit(c))</code> .
<code>isalpha()</code>	Checks for an alphabetic character; in the standard C locale, it is equivalent to <code>(isupper(c) islower(c))</code> . In some locales, there may be additional characters for which <code>isalpha()</code> is true—letters that are neither uppercase nor lowercase.
<code>isascii()</code>	Checks whether <code>c</code> is a 7-bit unsigned <code>char</code> value that fits into the ASCII character set. This function is a BSD extension and is also an SVID extension.
<code>isblank()</code>	Checks for a blank character; that is, a space or a tab. This function is a GNU extension.
<code>iscntrl()</code>	Checks for a control character.
<code>isdigit()</code>	Checks for a digit (0 through 9).
<code>isgraph()</code>	Checks for any printable character except space.
<code>islower()</code>	Checks for a lowercase character.
<code>isprint()</code>	Checks for any printable character, including space.
<code>ispunct()</code>	Checks for any printable character that is not a space or an alphanumeric character.
<code>isspace()</code>	Checks for whitespace characters. They are space, form-feed (<code>'\f'</code>), newline (<code>'\n'</code>), carriage return (<code>'\r'</code>), horizontal tab (<code>'\t'</code>), and vertical tab (<code>'\v'</code>).
<code>isupper()</code>	Checks for an uppercase letter.
<code>isxdigit()</code>	Checks for a hexadecimal digit (that is, one of 0 1 2 3 4 5 6 7 8 9 0 a b c d e f A B C D E F).

RETURN VALUE

The values returned are nonzero if the character `c` falls into the tested class, and `0` if it does not.

CONFORMS TO

ANSI C, BSD 4.3. `isascii()` is a BSD extension and is also an SVID extension. `isblank()` is a GNU extension.

BUGS

The details of what characters belong in which class depend on the current locale. For example, `isupper()` will not recognize an A with an umlaut (Ä) as an uppercase letter in the default C locale.

isinf, isnan, finite

isinf, isnan, finite—Test for infinity or not-a-number (NaN)

SYNOPSIS

```
#include <math.h>
int isinf(double value);
int isnan(double value);
int finite(double value);
```

DESCRIPTION

The `isinf()` function returns `-1` if `value` represents negative infinity, `1` if `value` represents positive infinity, and `0` otherwise.

The `isnan()` function returns a nonzero value if `value` is not-a-number (NaN), and `0` otherwise.

The `finite()` function returns a nonzero value if `value` is finite or is not a not-a-number (NaN) value, and `0` otherwise.

CONFORMS TO

BSD 4.3

GNU, 2 June 1993

j0, j1, jn, y0, y1, yn

j0, j1, jn, y0, y1, yn—Bessel functions

SYNOPSIS

```
#include <math.h>
double j0(double x);
double j1(double x);
double jn(int n, double x);
double y0(double x);
double y1(double x);
double yn(int n, double x);
```

DESCRIPTION

The `j0()` and `j1()` functions return Bessel functions of `x` of the first kind of orders 0 and 1, respectively. The `jn()` function returns the Bessel function of `x` of the first kind of order `n`.

The `y0()` and `y1()` functions return Bessel functions of `x` of the second kind, orders 0 and 1, respectively. The `yn()` function returns the Bessel function of `x` of the second kind, order `n`.

For the functions `y0()`, `y1()` and `yn()`, the value of `x` must be positive. For negative values of `x`, these functions return `-HUGE_VAL`.

CONFORMS TO

SVID 3, BSD 4.3

BUGS

There are errors of up to $2e-16$ in the values returned by `j0()`, `j1()`, and `jn()` for values of x between -8 and 8 .

26 June 1993

killpg

`killpg`—Sends a signal to all members of a process group

SYNOPSIS

```
#include <signal.h>
int killpg(pid_t pidgrp, int signal);
```

DESCRIPTION

The `killpg()` function causes the signal `signal` to be sent to all the processes in the process group `pidgrp` or to the processes' own process group if `pidgrp` is equal to `0`.

It is equivalent to `kill(-pidgrp, signal);`.

RETURN VALUE

The value returned is -1 on error, or 0 for success.

ERRORS

Errors are returned in `errno` and can be one of the following:

EINVAL	Signal is invalid.
ESRCH	Process group does not exist.
EPERM	The user ID of the calling process is not equal to that of the process the signal is sent to, and the user ID is not that of the super-user.

SEE ALSO

DESCRIPTION

`libinn` is a library of utility routines for manipulating Usenet articles and related data. It is not necessary to use the header file `libinn.h`; if it is not available, it is only necessary to properly declare the `TIMEINFO` datatype, as shown in the preceding code.

`GenerateMessageID` uses the current time, process ID, and fully qualified domain name of the local host to create a Message ID header that is highly likely to be unique. The returned value points to static space that is reused on subsequent calls.

`HeaderCleanFrom` removes the extraneous information from the value of a `From` or `Reply-To` header and leaves just the official mailing address. In particular, the following transformations are made to the `from` parameter:

```

address -> address
address (stuff) -> address
stuff <address>-> address

```

The transformations are simple and are based on RFC 1036, which limits the format of the header.

`HeaderFind` searches through `Article` looking for the specified `Header`. `size` should be the length of the header name. It returns a pointer to the value of the header, skipping leading whitespace, or `NULL` if the header cannot be found. `Article` should be a standard C string containing the text of the article; the end of a header is indicated by a blank line: two consecutive `\n` characters.

`CAopen` and `CAClose` provide news clients with access to the active file; the `CA` stands for Client Active. `CAopen` opens the `active(5)` file for reading. It returns a pointer to an open `FILE`, or `NULL` on error. If a local or an NFS-mounted copy exists, `CAopen` will use that file. The `FromServer` and `ToServer` parameters should be `FILES` connected to the NNTP server for input and output, respectively. (See the discussions of `NNTPremoteopen` and `NNTPlocalopen` later in this section.) If either parameter is `NULL`, `CAopen` will just return `NULL` if the file is not locally available. If neither is `NULL`, `CAopen` will use them to query the NNTP server using the “list” command to make a local temporary copy.

The `CAlistopen` sends a “list” command to the server and returns a temporary file containing the results. The `request` parameter, if not `NULL`, will be sent as an argument to the command. Unlike `CAopen`, this routine will never use a locally available copy of the active file.

`CAClose` closes the active file and removes any temporary file that might have been created by `CAopen` or `CAlistopen`.

`CloseOnExec` can make a descriptor *close-on-exec* so that it is not shared with any child processes. If the flag is nonzero, the file is so marked; if it is 0, the close-on-exec mode is cleared.

`DDstart`, `DDcheck`, and `DDend` are used to set the `Distribution` header; the `DD` stands for Default Distribution. The `distrib.pats(5)` file is consulted to determine the proper value for the `Distribution` header after all newsgroups have been checked. `DDstart` begins the parsing. It returns a pointer to an opaque handle that should be used on subsequent calls. The `FromServer` and `ToServer` parameters should be `FILES` connected to the NNTP server for input and output, respectively. If either parameter is `NULL`, an empty default will ultimately be returned if the file is not locally available.

`DDcheck` should be called with the handle, `h`, returned by `DDstart` and a new group, `group`, to check. It can be called as often as necessary.

`DDend` releases any state maintained in the handle and returns an allocated copy of the text that should be used for the `Distribution` header.

`SetNonBlocking` enables (if `flag` is nonzero) or disables (if `flag` is 0) non-blocking I/O on the indicated descriptor. It returns -1 on failure and 0 on success.

`LockFile` tries to lock the file descriptor `fd`. If `flag` is nonzero it will block until the lock can be made; otherwise it will return -1 if the file cannot be locked. It returns -1 on failure and 0 on success.

`GetConfigValue` returns the value of the specified configuration parameter. (See `inn.conf(5)` for details on the parameters and their interpretation.) The returned value points to static space that is reused on subsequent calls.

`GetFileConfigValue` returns the specified configuration parameter from the `inn.conf` file without checking for any defaults. The returned value points to static space that is reused on subsequent calls, or `NULL` if the value is not present.

`GetFQDN` returns the fully qualified domain name of the local host. The returned value points to static space that is reused on subsequent calls, or `NULL` on error.

`GetModeratorAddress` returns the mailing address of the moderator for the specified group or `NULL` on error. (See `moderators(5)` for details on how the address is determined.) `GetModeratorAddress` does no checking to see if the specified group is actually moderated. The returned value points to static space that is reused on subsequent calls.

`GetResourceUsage` fills in the `usertime` and `system` parameters with the total user and system time used by the current process and any children it may have spawned. It gets the values by doing a `times(2)` system call. It returns -1 on failure, or 0 on success.

`GetTimeInfo` fills in the `now` parameter with information about the current time and `tzzone`. The `time` and `usec` fields will be filled in by a call to `gettimeofday(2)`. The `time` field will be filled in by a call to `time(2)`, and the `usec` field will be set to 0. The `tzzone` field will be filled in with the current offset from GMT. This is done by calling `localtime(3)` and taking the value of the `tm_gmtoff` field, negating it, and dividing it by 60. This is done by calling `localtime(3)` and comparing the value with that returned by a call to `gmtime(3)`. For efficiency, the `tzzone` field is only recalculated if more than an hour has passed since the last time `GetTimeInfo` was called. This routine returns -1 on failure, and 0 on success.

`NNTPlocalopen` opens a connection to the private port of an InterNetNews server running on the local host. It returns -1 on failure, or 0 on success. `FromServerp` and `ToServerp` will be filled in with `FILES` that can be used to communicate with the server. `errbuff` can either be `NULL` or a pointer to a buffer at least 512 bytes long. If it is not `NULL`, and the server refuses the connection, it will be filled in with the text of the server's reply. This routine is not for general use; it is a subroutine for compatibility with systems that have UNIX-domain stream sockets. It always returns -1.

`NNTPremoteopen` does the same as `NNTPlocalopen`, except that it calls `GetConfigValue` to find the name of the local server and opens a connection to the standard NNTP port. Any client program can use this routine. It returns -1 on failure, or 0 on success.

`NNTPconnect` is the same as `NNTPremoteopen`, except that the desired host is given as the `host` parameter.

`NNTPcheckarticle` verifies that the text meets the NNTP limitations on line length. It returns -1 on failure, or 0 if the text is valid.

`NNTPsendarticle` writes text on `ToServer` using NNTP conventions for line termination. The text should consist of one or more lines ending with a newline. If `Terminate` is nonzero, the routine will also write the NNTP data-termination marker on the stream. It returns `-1` on failure, or `0` on success.

`NNTPsendpassword` sends authentication information to an NNTP server by finding the appropriate entry in the `passwd.nntp(5)` file. `server` contains the name of the host; `GetConfigValue` will be used if `server` is `NULL`. `FromServer` and `ToServer` should be `FILES` that are connected to the server. No action is taken if the specified host is not listed in the password file.

`Radix32` converts the number in `value` into a radix-32 string in the buffer pointed to by `p`. The number is split into five-bit pieces, and each piece is converted into a character using the alphabet `0...9a...v` to represent the numbers 0–32. Only the lowest 32 bits of `value` are used, so `p` need only point to a buffer of eight bytes (seven characters and the trailing `\0`).

`ReadInFile` reads the file named `name` into allocated memory, appending a terminating `\0` byte. It returns a pointer to the space, or `NULL` on error. If `Sbp` is not `NULL`, it is taken as the address of a place to store the results of a `stat(2)` call.

`ReadInDescriptor` performs the same function as `ReadInFile`, except that `fd` refers to an already-open file.

`INNVersion` returns a pointer to a string identifying the INN version, suitable for printing in logon banners.

EXAMPLES

```
char *p;
char *Article;
char buff[256];
FILE *F;
FILE *ToServer;
FILE *FromServer;
if ((p = HeaderFind(Article, "From", 4)) == NULL)
    Fatal("Can't find From line");
(void)strcpy(buff, p);
HeaderCleanFrom(buff);
if ((F = CAopen(FromServer, ToServer)) == NULL)
    Fatal("Can't open active file");
/* Don't pass the file on to our children. */
CloseOnExec(fileno(F), 1);
/* Make a local copy. */
p = ReadInDescriptor(fileno(F), (struct stat *)NULL);
/* Close the file. */
CAclose();
if (NNTPremoteopen(&FromServer, &ToServer) < 0)
    Fatal("Can't connect to server");
if ((p = GetModeratorAddress("comp.sources.unix")) == NULL)
    Fatal("Can't find moderator's address");
```

libpbm

`libpbm`—Functions to support portable bitmap programs

SYNOPSIS

```
#include <pbm.h>
cc ... libpbm.a
```

DESCRIPTION—PACKAGEWIDE ROUTINES

The following sections describe string and file management routines available in `libpbm`.

KEYWORD MATCHING

The following does a case-insensitive match of `str` against `keyword`:

```
int pm_keymatch( char* str, char* keyword, int mi nchars )
```

`str` can be a leading substring of `keyword`, but at least `mi nchars` must be present.

LOG BASE TWO

This converts between a `maxval` and the minimum number of bits required to hold it:

```
int pm_maxvaltobits(int maxval )
int pm_bitstomaxval(int bits)
```

MESSAGES AND ERRORS

This is a `printf()`-style routine to write an informational message:

```
void pm_message(char* fmt, ... )
```

This is a `printf()` style routine to write an error message and abort:

```
void pm_error(char* fmt, ... )
```

The following writes a usage message; the string should indicate what arguments are to be provided to the program:

```
void pm_usage(char* usage)
```

GENERIC FILE MANAGEMENT

The following opens the given file for reading, with appropriate error checking:

```
FILE* pm_openr(char* name)
```

A filename of `-` is taken as equivalent to `stdin`.

The following opens the given file for writing, with appropriate error checking:

```
FILE* pm_openw(char* name)
```

The following closes the file descriptor, with appropriate error checking:

```
void pm_close(FILE* fp)
```

ENDIAN I/O

The following are routines to read and write short and long ints in either big- or little-endian byte order:

```
int pm_readbigshort(FILE* in, short* sP)
int pm_writebigshort(FILE* out, short s)
int pm_readbiglong(FILE* in, long* lP)
int pm_writebiglong(FILE* out, long l)
int pm_readlittleshort(FILE* in, short* sP)
int pm_writelittleshort(FILE* out, short s)
int pm_readlittlelong(FILE* in, long* lP)
int pm_writelittlelong(FILE* out, long l)
```

DESCRIPTION—PBM-SPECIFIC ROUTINES

The following sections describe file management routines available in `libpbm`.

TYPES AND CONSTANTS

Each bit should contain only the values of `PBM_WHITE` or `PBM_BLACK`:

```
typedef ... bit;
#define PBM_WHITE ...
#define PBM_BLACK ...
```

These are routines for distinguishing different file formats and types:

```
#define PBM_FORMAT ...
#define RPBM_FORMAT ...
#define PBM_TYPE PBM_FORMAT
#define PBM_FORMAT TYPE(f) ...
```

INITIALIZATION

All PBM programs must call this routine:

```
void pbm_init(int* argcP, char* argv[] )
```

MEMORY MANAGEMENT

This allocates an array of bits:

```
bit** pbm_allocarray(int cols, int rows)
```

This allocates a row of the given number of bits:

```
bit* pbm_allocrow(int cols)
```

This frees the array allocated with `pbm_allocarray()` containing the given number of rows:

```
void pbm_freearray(bit** bits, int rows)
```

This frees a row of bits:

```
void pbm_freerow(bit* bitrow)
```

READING FILES

This reads the header from a PBM file, filling in the `rows`, `cols`, and `format` variables:

```
void pbm_readpbminit(FILE* fp, int* colsP, int* rowsP, int* formatP)
```

This reads a row of bits into the `bitrow` array (`format` and `cols` are filled in by `pbm_readpbminit()`):

```
void pbm_readpbmrow(FILE* fp, bit* bitrow, int cols, int format)
```

This function combines `pbm_readpbminit()`, `pbm_allocarray()`, and `pbm_readpbmrow()`:

```
bit** pbm_readpbm(FILE* fp, int* colsP, int* rowsP)
```

It reads an entire bitmap file into memory, returning the allocated array and filling in the `rows` and `cols` variables.

This reads an entire file or input stream of unknown size to a buffer and allocates more memory as needed:

```
char* pm_read_unknown_size(FILE* fp, long* nread)
```

The calling routine has to free the allocated buffer with `free()`. `pm_read_unknown_size()` returns a pointer to the allocated buffer; the `nread` argument returns the number of bytes read.

WRITING FILES

This writes the header for a portable bitmap file:

```
void pbm_writepbminit(FILE* fp, int cols, int rows, int forceplain)
```

The `forceplain` flag forces a plain-format file to be written, as opposed to a raw-format one.

This writes a row from a portable bitmap:

```
void pbm_writepbmrow(FILE* fp, bit* bitrow, int cols, int forceplain)
```

This writes the header and all data for a portable bitmap:

```
void pbm_writepbm(FILE* fp, bit** bits, int cols, int rows, int forceplain)
```

This function combines `pbm_writepbminit()` and `pbm_writepbmrow()`.

libpgm

libpgm—Functions to support portable graymap programs

SYNOPSIS

```
#include <pgm.h>
cc ... libpgm.a libpbm.a
```

DESCRIPTION

The following sections describe memory and file management routines available in `libpgm`.

TYPES AND CONSTANTS

Each gray should contain only the values between 0 and `PGM_MAXMAXVAL`.

`pgm_pbmmaxval` is the `maxval` used when a PGM program reads a PBM file. Normally it is 1, but for some programs, a larger value gives better results.

```
typedef ... gray;
#define PGM_MAXMAXVAL ...
extern gray pgm_pbmmaxval;
```

The following are for distinguishing different file formats and types:

```
#define PGM_FORMAT ...
#define RPGM_FORMAT ...
#define PGM_TYPE PGM_FORMAT
int PGM_FORMAT_TYPE(int format)
```

INITIALIZATION

All PGM programs must call this routine:

```
void pgm_init(int* argcP, char* argv[])
```

MEMORY MANAGEMENT

This allocates an array of grays:

```
gray** pgm_allocarray(int cols, int rows)
```

This allocates a row of the given number of grays:

```
gray* pgm_allocrow(int cols)
```

This frees the array allocated with `pgm_allocarray()` containing the given number of rows:

```
void pgm_freearray(gray** grays, int rows)
```

This frees a row of grays:

```
void pgm_freerow(gray* grayrow)
```

READING FILES

This reads the header from a PGM file, filling in the `rows`, `cols`, `maxval`, and `format` variables:

```
void pgm_readpgminit(FILE* fp, int* colsP, int* rowsP, gray* maxvalP,
int* formatP)
```

This reads a row of grays into the `grayrow` array. `format`, `cols`, and `maxval` are filled in by `pgm_readpgminit()`:

```
void pgm_readpgmrow(FILE* fp, gray* grayrow, int cols, gray maxval, int format)
```

This function combines `pgm_readpgminit()`, `pgm_allocarray()`, and `pgm_readpgmrow()`:

```
gray** pgm_readpgm(FILE* fp, int* colsP, int* rowsP, gray* maxvalP)
```

It reads an entire graymap file into memory, returning the allocated array and filling in the `rows`, `cols`, and `maxval` variables.

WRITING FILES

This writes the header for a portable graymap file:

```
void pgm_writepgminit( FILE* fp, int cols, int rows, gray maxval,
int forceplain )
```

The `forceplain` flag forces a plain-format file to be written, as opposed to a raw-format one.

This writes a row from a portable graymap:

```
void pgm_writepgmrow(FILE* fp, gray* grayrow, int cols, gray maxval,
int forceplain)
```

This function combines `pgm_writepgminit()` and `pgm_writepgmrow()`; it writes the header and all data for a portable graymap:

```
void pgm_writepgm( FILE* fp, gray** grays, int cols, int rows, gray maxval, int forceplain)
```

libpnm

`libpnm`—Functions to support portable anymap programs

SYNOPSIS

```
#include <pnm.h>
cc ... libpnm.a libppm.a libpgm.a libpbm.a
```

DESCRIPTION

The following sections describe memory and file management routines available in `libpnm`.

TYPES AND CONSTANTS

Each `xel` contains three `xelvals`, each of which should contain only a value between 0 and `PNM_MAXMAXVAL`. `pnm_pbmmaxval` is the `maxval` used when a PNM program reads a PBM file. Normally it is 1, but for some programs, a larger value gives better results.

```
typedef ... xel;
typedef ... xelval;
#define PNM_MAXMAXVAL ...
extern xelval pnm_pbmmaxval;
```

XEL MANIPULATIONS

This macro extracts a single value from an `xel` when you know it's from a PBM or PGM file:

```
xelval PNM_GET1( xel x )
```

When the `xel` is from a PPM file, use `PPM_GETR()`, `PPM_GETG()`, and `PPM_GETB()`.

This macro assigns a single value to an `xel` when you know it's from a PBM or PGM file:

```
void PNM_ASSIGN1( xel x, xelval v )
```

When the `xel` is from a PPM file, use `PPM_ASSIGN()`.

This macro checks two `xels` for equality:

```
int PNM_EQUAL( xel x, xel y )
```

This one is for distinguishing different file types:

```
int PNM_FORMAT_TYPE( int format )
```

INITIALIZATION

All PNM programs must call this routine:

```
void pnm_init( int* argcP, char* argv[] )
```

MEMORY MANAGEMENT

This allocates an array of `xels`:

```
xel** pnm_allocarray( int cols, int rows )
```

This allocates a row of the given number of `xels`:

```
xel* pnm_allocrow( int cols )
```

This frees the array allocated with `pnm_allocarray()` that contains the given number of rows:

```
void pnm_freearray( xel** xels, int rows )
```

This frees a row of `xels`:

```
void pnm_freerow( xel* xelrow )
```

READING FILES

This reads the header from a PNM file, filling in the `rows`, `cols`, `maxval`, and `format` variables:

```
void pnm_readpnmint( FILE* fp, int* colsP, int* rowsP, xelval* maxvalP,
int* formatP )
```

This reads a row of `xels` into the `xelrow` array. `format`, `cols`, and `maxval` are filled in by `pnm_readpnmint()`:

```
void pnm_readpnmrow( FILE* fp, xel* xelrow, int cols, xelval maxval, int format )
```

This reads an entire anymap file into memory, returning the allocated array and filling in the `rows`, `cols`, `maxval`, and `format` variables:

```
xel** pnm_readpnm( FILE* fp, int* colsP, int* rowsP, xelval* maxvalP,
int* formatP )
```

This function combines `pnm_readpnmint()`, `pnm_allocarray()`, and `pnm_readpnmrow()`. Unlike the equivalent functions in PBM, PGM, and PPM, it returns the format so you can tell what type the file is.

WRITING FILES

This writes the header for a portable anymap file:

```
void pnm_writepnmint( FILE* fp, int cols, int rows, xelval maxval, int format,
int force-plain)
```

Unlike the equivalent functions in PBM, PGM, and PPM, you have to specify the output type. The `forceplain` flag forces a plain-format file to be written, as opposed to a raw-format one.

This writes a row from a portable anymap:

```
void pnm_writenmrow( FILE* fp, xel* xelrow, int cols, xelval maxval, int format,
int forceplain )
```

This writes the header and all data for a portable anymap:

```
void pnm_writenm( FILE* fp, xel** xels, int cols, int rows, xelval maxval, int format,
int forceplain )
```

This function combines `pnm_writenminit()` and `pnm_writenmrow()`.

FORMAT PROMOTION

This promotes a row of xels from one `maxval` and `format` to a new set:

```
void pnm_promoteformatrow( xel* xelrow, int cols, xelval maxval, int format, xelval new-maxval,
int newformat )
```

Use this when combining multiple anymaps of different types—just take the maximum value of the `maxvals` and the max of the `formats`, and promote them all to that.

This promotes an entire anymap:

```
void pnm_promoteformat( xel** xels, int cols, int rows, xelval maxval,
int format, xelval newmaxval, int newformat )
```

XEL MANIPULATION

These return a white or black `xel`, respectively, for the given `maxval` and `format`:

```
xel pnm_whitexel( xelval maxval, int format )
xel pnm_blackxel( xelval maxval, int format )
```

This inverts an `xel`:

```
void pnm_invertxel( xel* x, xelval maxval, int format )
```

This figures out an appropriate background `xel` based on this row:

```
xel pnm_backgroundxelrow( xel* xelrow, int cols, xelval maxval, int format )
```

This figures out a background `xel` based on an entire anymap:

```
xel pnm_backgroundxel( xel** xels, int cols, int rows, xelval maxval,
int format )
```

This can do a slightly better job than `pnm_backgroundxelrow()`.

libppm

libppm—Functions to support portable pixmap programs

SYNOPSIS

```
#include <ppm.h>
cc ... libppm.a libpbgm.a libpbm.a
```

TYPES AND CONSTANTS

```
typedef ... pixel;
typedef ... pixval;
#define PPM_MAXMAXVAL ...
extern pixval ppm_pbmmmaxval;
```

Each pixel contains three `pixvals`, each of which should contain only the values between 0 and `PPM_MAXMAXVAL`. `ppm_pbmmmaxval` is the `maxval` used when a PPM program reads a PBM file. Normally it is 1; however, for some programs, a larger value gives better results.

For distinguishing different file formats and types, use

```
#define PPM_FORMAT ...
#define RPPM_FORMAT ...
#define PPM_TYPE PPM_FORMAT
int PPM_FORMAT_TYPE( int format )
```

These three macros retrieve the red, green, or blue value from the given pixel:

```
pixval PPM_GETR( pixel p )
pixval PPM_GETG( pixel p )
pixval PPM_GETB( pixel p )
```

This macro assigns the given red, green, and blue values to the pixel:

```
void PPM_ASSIGN( pixel p, pixval red, pixval grn, pixval blu )
```

This macro checks two pixels for equality:

```
int PPM_EQUAL( pixel p, pixel q )
```

The following macro scales the colors of pixel `p` according to the old and new maximum values and assigns the new values to `newp`. It is intended to make writing `ppm` to whatever easier.

```
void PPM_DEPTH( pixel newp, pixel p, pixval oldmaxval, pixval newmaxval )
```

This macro determines the luminance of the pixel `p`:

```
float PPM_LUMIN( pixel p )
```

MEMORY MANAGEMENT

Allocate an array of pixels:

```
pixel** ppm_allocarray( int cols, int rows )
```

Allocate a row of the given number of pixels:

```
pixel* ppm_allocrow( int cols )
```

Free the array allocated with `ppm_allocarray()` containing the given number of rows:

```
void ppm_freearray( pixel** pixels, int rows )
```

Free a row of pixels:

```
void ppm_freerow( pixel* pixelrow )
```

READING PBM FILES

```
void ppm_readppminit( FILE* fp, int* colsP, int* rowsP, pixval* maxvalP, int* formatP )
```

Read the header from a PPM file, filling in the rows, cols, maxval, and format variables.

```
void ppm_readppmrow( FILE* fp, pixel* pixelrow, int cols, pixval maxval, int format )
```

Read a row of pixels into the pixelrow array. Format, cols, and maxval were filled in by ppm_readppminit().

```
pixel** ppm_readppm( FILE* fp, int* colsP, int* rowsP, pixval* maxvalP )
```

Read an entire pixmap file into memory, returning the allocated array and filling in the rows, cols, and maxval variables. This function combines ppm_readppminit(), ppm_allocarray(), and ppm_readppmrow().

WRITING FILES

```
void ppm_writeppminit( FILE* fp, int cols, int rows, pixval maxval, int forceplain )
```

Write the header for a portable pixmap file. The forceplain flag forces a plain-format file to be written, as opposed to a raw-format one.

```
void ppm_writeppmrow( FILE* fp, pixel* pixelrow, int cols, pixval maxval, int forceplain)
```

Write a row from a portable pixmap.

```
void ppm_writeppm( FILE* fp, pixel** pixels, int cols, int rows, pixval maxval, int force-plain)
```

Write the header and all data for a portable pixmap. This function combines ppm_writeppminit() and ppm_writeppmrow().

COLOR NAMES

This line parses an ASCII color name into a pixel:

```
pixel ppm_parsecolor( char* colorname, pixval maxval )
```

The color can be specified in three ways: as a name, assuming that a pointer to an X11-style color names file was compiled in; as an X11-style hexadecimal number (#rgb, #rrggbb, #rrrgggbbb, or #rrrrggggbbb); or as a triplet of decimal floating point numbers separated by commas (r.r,g.g,b.b).

This line returns a pointer to a string describing the given color:

```
char* ppm_colorname( pixel* colorP, pixval maxval, int hexok )
```

If the X11 color names file is available and the color appears in it, that name is returned. Otherwise, if the hexok flag is true, then a hexadecimal colorspec is returned; if hexok is false and the X11 color names file is available, then the closest matching color is returned; otherwise, it's an error.

localeconv

localeconv—Gets numeric formatting information

SYNOPSIS

```
#include <locale.h>
struct lconv *localeconv(void);
```

DESCRIPTION

The `localeconf()` function returns a string to a `struct lconv` for the current locale.

CONFORMS TO

This command conforms to ANSI C and POSIX.1.

Linux supports the portable locales C and POSIX and also the European Latin-1 ISO-8859-1, and Russian KOI-8 locales.

The `printf()` family of functions may or may not honor the current locale.

SEE ALSO

GNU, 25 April 1993

longjmp

`longjmp`—Nonlocal jump to a saved stack context

SYNOPSIS

```
#include <setjmp.h>
void longjmp(jmp_buf env,int val);
```

DESCRIPTION

`longjmp()` and `setjmp(3)` are useful for dealing with errors and interrupts encountered in a low-level subroutine of a program. `longjmp()` restores the environment saved by the last call of `setjmp()` with the corresponding `env` argument. After `longjmp()` is completed, program execution continues as if the corresponding call of `setjmp()` had just returned the value `val`. `longjmp()` cannot cause 0 to be returned. If `longjmp` is invoked with a second argument of 0, 1 will be returned instead.

RETURN VALUE

This function never returns.

CONFORMS TO

POSIX

NOTES

POSIX does not specify if the signal context will be restored or not. If you want to save restore signal masks, use `siglongjmp(3)`. `longjmp()` makes programs hard to understand and maintain. If possible, an alternative should be used.

SEE ALSO

`setjmp(3)`, `sigsetjmp(2)`, `siglongjmp(2)`

25 November 1994

lfind, lsearch

`lfind, lsearch`—Linear search of an array

SYNOPSIS

```
#include <stdlib.h>
void *lfind(const void *key, const void *base, size_t *nmemb,
```

```
size_t size,int(*compar)(const void *, const void *));
void *lsearch(const void *key, const void *base, size_t *nmemb,
size_t size,int(*compar)(const void *, const void *));
```

DESCRIPTION

`lfind()` and `lsearch()` perform a linear search for `key` in the array `base`, which has `*nmemb` elements of size bytes each. The comparison function referenced by `compar` is expected to have two arguments that point to the key object and to an array member, in that order, and which returns zero if the key object matches the array member, and non-zero otherwise.

If `lsearch()` does not find a matching element, then the key object is inserted at the end of the table, and `*nmemb` is incremented.

RETURN VALUE

`lfind()` returns a pointer to a matching member of the array, or `NULL` if no match is found. `lsearch()` returns a pointer to a matching member of the array, or to the newly added member if no match is found.

calloc, malloc, free, realloc

`calloc`, `malloc`, `free`, `realloc`—Allocate and free dynamic memory

SYNOPSIS

```
#include <stdlib.h>
void *calloc(size_t nmemb, size_t size);
void *malloc(size_t size);
void free(void *ptr);
void *realloc(void *ptr, size_t size);
```

DESCRIPTION

`calloc()` allocates memory for an array of `nmemb` elements of `size` bytes each and returns a pointer to the allocated memory. The memory is set to zero.

`malloc()` allocates `size` bytes and returns a pointer to the allocated memory. The memory is not cleared.

`free()` frees the memory space pointed to by `ptr`, which must have been returned by a previous call to `malloc()`, `calloc()` or `realloc()`. If `ptr` is `NULL`, no operation is performed.

`realloc()` changes the size of the memory block pointed to by `ptr` to `size` bytes. The contents will be unchanged to the minimum of the old and new sizes; newly allocated memory will be uninitialized. If `ptr` is `NULL`, the call is equivalent to `malloc(size)`; if `size` is equal to zero, the call is equivalent to `free(ptr)`. Unless `ptr` is `NULL`, it must have been returned by an earlier call to `malloc()`, `calloc()`, or `realloc()`.

RETURN VALUES

For `calloc()` and `malloc()`, the value returned is a pointer to the allocated memory, which is suitably aligned for any kind of variable, or `NULL` if the request fails.

`free()` returns no value.

`realloc()` returns a pointer to the newly allocated memory, which is suitably aligned for any kind of variable and may be different from `ptr`, or `NULL` if the request fails or if `size` was equal to 0. If `realloc()` fails, the original block is left untouched; it is not freed or moved.

mblen

`mblen`—Determines the number of bytes in a character

SYNOPSIS

```
#include <stdlib.h>
int mblen(const char *s, size_t n);
```

DESCRIPTION

The `mblen()` function scans the first `n` bytes of the string `s` and returns the number of bytes in a character. The `mblen()` function is equivalent to

```
mbtowc((wchar_t*)0, s, n);
```

except that the shift state of the `mbtowc()` function is not affected.

RETURN VALUE

The `mblen()` returns the number of bytes in a character, or `-1` if the character is invalid, or `0` if it is a `NULL` string.

CONFORMS TO

SVID 3, ISO 9899

mbstowcs

`mbstowcs`—Converts a multibyte string to a wide character string

SYNOPSIS

```
#include <stdlib.h>
size_t mbstowcs(wchar_t *pwcs, const char *s, size_t n);
```

DESCRIPTION

The `mbstowcs()` function converts a sequence of multibyte characters from the array `s` into a sequence of wide characters and stores up to `n` wide characters in the array `pwcs`.

RETURN VALUE

`mbstowcs()` returns the number of wide characters stored, or `-1` if `s` contains an invalid multibyte character.

CONFORMS TO

SVID 3, ISO 9899

mbtowc

`mbtowc`—Converts a multibyte character to a wide character

SYNOPSIS

```
#include <stdlib.h>
int mbtowc(wchar_t *pwc, const char *s, size_t n);
```

DESCRIPTION

The `mbtowc()` function converts a multibyte character `s`, which is no longer than `n` bytes, into a wide character and, if `pwc` is not `NULL`, stores the wide character in `pwc`.

RETURN VALUE

`mbtowc()` returns the number of bytes in the multibyte character, or `-1` if the multibyte character is not valid.

CONFORMS TO

memccpy

`memccpy`—Copies memory area

SYNOPSIS

```
#include <string.h>
void *memccpy(void *dest, const void *src, int c, size_t n);
```

DESCRIPTION

The `memccpy()` function copies no more than `n` bytes from memory area `src` to memory area `dest`, stopping when the character `c` is found.

RETURN VALUE

The `memccpy()` function returns a pointer to the next character in `dest` after `c`, or `NULL` if `c` was not found in the first `n` characters of `src`.

CONFORMS TO

SVID 3, BSD 4.3

SEE ALSO

bcopy(3), memcpy(3), memmove(3), strcpy(3), strncpy(3)

memchr

memchr—Scans memory for a character

SYNOPSIS

```
#include <string.h>
void *memchr(const void *s, int c, size_t n);
```

DESCRIPTION

The `memchr()` function scans the first `n` bytes of the memory area pointed to by `s` for the character `c`. The first byte to match `c` (interpreted as an unsigned character) stops the operation.

RETURN VALUE

The `memchr()` function returns a pointer to the matching byte or `NULL` if the character does not occur in the given memory area.

CONFORMS TO

SVID 3, BSD 4.3, ISO 9899

SEE ALSO

index(3), rindex(3), strchr(3), strpbrk(3), strrchr(3), strsep(3), strspn(3), strstr(3)

memcmp

memcmp—Compares memory areas

SYNOPSIS

```
#include <string.h>
int memcmp(const void *s1, const void *s2, size_t n);
```

DESCRIPTION

The `memcmp()` function compares the first `n` bytes of the memory areas `s1` and `s2`. It returns an integer less than, equal to, or greater than zero if `s1` is found, respectively, to be less than, to match, or to be greater than `s2`.

RETURN VALUE

The `memcmp()` function returns an integer less than, equal to, or greater than zero if the first `n` bytes of `s1` is found, respectively, to be less than, to match, or be greater than the first `n` bytes of `s2`.

CONFORMS TO

memcpy

`memcpy`—Copies memory area

SYNOPSIS

```
#include <string.h>
void *memcpy(void *dest, const void *src, size_t n);
```

DESCRIPTION

The `memcpy()` function copies `n` bytes from memory area `src` to memory area `dest`. The memory areas may not overlap. Use `memmove(3)` if the memory areas do overlap.

RETURN VALUE

The `memcpy()` function returns a pointer to `dest`.

CONFORMS TO

memfrob

`memfrob`—Frobnicates (encrypts) a memory area

SYNOPSIS

```
#include <string.h>
void *memfrob(void *s, size_t n);
```

DESCRIPTION

The `memfrob()` function encrypts the first `n` bytes of the memory area `s` by using exclusive OR on each character with the number 42. The effect can be reversed by using `memfrob()` on the encrypted memory area.

Note that this function is not a proper encryption routine as the XOR constant is fixed, and is only suitable for hiding strings.

RETURN VALUE

The `memfrob()` function returns a pointer to the encrypted memory area.

CONFORMS TO

The `memfrob()` function is unique to the Linux C Library and GNU C Library.

SEE ALSO

`strfry(3)`

GNU, 12 April 1993

memmem

`memmem`—Locates a substring

SYNOPSIS

```
#include <string.h>
void *memmem(const void *needle, size_t needlelen,
             const void *haystack, size_t haystacklen);
```

DESCRIPTION

The `memmem()` function finds the first occurrence of the substring `needle` of length `needlelen` in the memory area `haystack` of length `haystacklen`.

RETURN VALUE

The `memmem()` function returns a pointer to the beginning of the substring, or `NULL` if the substring is not found.

SEE ALSO

`strstr(3)`

GNU, 11 April 1993

memmove

`memmove`—Copies memory area

SYNOPSIS

```
#include <string.h>
void *memmove(void *dest, const void *src, size_t n);
```

DESCRIPTION

The `memmove()` function copies `n` bytes from memory area `src` to memory area `dest`. The memory areas may overlap.

RETURN VALUE

The `memmove()` function returns a pointer to `dest`.

mkfifo

`mkfifo`—Makes a FIFO special file (a named pipe)

SYNOPSIS

```
#include <sys/types.h>
#include <sys/stat.h>
int mkfifo ( const char *pathname, mode_t mode );
```

DESCRIPTION

`mkfifo` makes a FIFO special file with name `pathname`. `mode` specifies the FIFO's permissions. It is modified by the process's `umask` in the usual way: the permissions of the created file are `(mode&umask)`.

A FIFO special file is similar to a pipe, except that it is created in a different way. Instead of being an anonymous communications channel, a FIFO special file is entered into the filesystem by calling `mkfifo`.

After you have created a FIFO special file in this way, any process can open it for reading or writing, in the same way as an ordinary file. However, it has to be open at both ends simultaneously before you can proceed to do any input or output operations on it. Opening a FIFO for reading normally blocks until some other process opens the same FIFO for writing, and vice versa.

RETURN VALUE

The normal, successful return value from `mkfifo` is `0`. In the case of an error, `-1` is returned (in which case, `errno` is set appropriately).

ERRORS

EACCES
EEXIST

One of the directories in `pathname` did not allow search (execute) permission.
`pathname` already exists.

ENAMETOOLONG	Either the total length of <code>pathname</code> is greater than <code>PATH_MAX</code> , or an individual filename component has a length greater than <code>NAME_MAX</code> . In the GNU system, there is no imposed limit on overall filename length, but some filesystems may place limits on the length of a component.
ENOENT	A directory component in <code>pathname</code> does not exist or is a dangling symbolic link.
ENOSPC	The directory or filesystem has no room for the new file.
ENOTDIR	A component used as a directory in <code>pathname</code> is not, in fact, a directory.
EROFS	<code>pathname</code> refers to a read-only filesystem.

CONFORMS TO

POSIX.1

mkstemp

`mkstemp`—Creates a unique temporary file

SYNOPSIS

```
#include <unistd.h>
int *mkstemp(char *template);
```

DESCRIPTION

The `mkstemp()` function generates a unique temporary filename from `template`. The last six characters of `template` must be `xxxxxx` and these are replaced with a string that makes the filename unique. The file is then created with mode read/write and permissions `0666`.

RETURN VALUE

The `mkstemp()` function returns the file descriptor `fd` of the temporary file.

ERRORS

EINVAL	The last six characters of <code>template</code> were not <code>xxxxxx</code> .
EEXIST	The temporary file is not unique.

CONFORMS TO

BSD 4.3

asctime, ctime, difftime, gmtime, localtime, mktime

`asctime`, `ctime`, `difftime`, `gmtime`, `localtime`, `mktime`—Convert date and time to ASCII

SYNOPSIS

```
extern char *tzname[2];

void tzset()

#include <sys/types.h>

char *ctime(clock)
const time_t *clock;

double difftime(time1, time0)
time_t time1;
time_t time0;

#include <time.h>

char *asctime(tm)
const struct tm *tm;

struct tm *localtime(clock)
const time_t *clock;

struct tm *gmtime(clock)
const time_t *clock;

time_t mktime(tm)
struct tm *tm;

cc ... -lz
```

DESCRIPTION

`ctime` converts a long integer, pointed to by `clock`, representing the time in seconds since 00:00:00 UTC, January 1, 1970, and returns a pointer to a 26-character string of the form `Thu Nov 24 18:22:48 1986`. (Note: UTC is Coordinated Universal Time.) All the fields have constant width.

`localtime` and `gmtime` return pointers to `tm` structures, described in the following paragraphs. `localtime` corrects for the time zone and any time zone adjustments (such as Daylight Saving Time in the United States). Before doing so, `localtime` calls `tzset` (if `tzset` has not been called in the current process). After filling in the `tm` structure, `localtime` sets the `tm_isdst`'th element of `tzname` to a pointer to an ASCII string that's the time zone abbreviation to be used with `localtime`'s return value.

`gmtime` converts to Coordinated Universal Time.

`asctime` converts a time value contained in a `tm` structure to a 26-character string, as shown in the preceding example, and returns a pointer to the string.

`mktime` converts the broken-down time, expressed as local time, in the structure pointed to by `tm` into a calendar time value with the same encoding as that of the values returned by the `time` function. The original values of the `tm_wday` and `tm_yday` components of the structure are ignored, and the original values of the other components are not restricted to their normal ranges. (A positive or zero value for `tm_isdst` causes `mktime` to presume initially that summer time (for example, Daylight Saving Time in the United States) respectively, is or is not in effect for the specified time. A negative value for `tm_isdst` causes the `mktime` function to attempt to divine whether summer time is in effect for the specified time.) On successful completion, the values of the `tm_wday` and `tm_yday` components of the structure are set appropriately, and the other components are set to represent the specified calendar time, but with their values forced to their normal ranges; the final value of `tm_mday` is not set until `tm_mon` and `tm_year` are determined. `mktime` returns the specified calendar time; if the calendar time cannot be represented, it returns `-1`.

`difftime` returns the difference between two calendar times, (`time1` - `time0`), expressed in seconds.

Declarations of all the functions and externals, and the `tm` structure, are in the `<time.h>` header file. The structure (of type `struct tm`) includes the following fields:

```
int tm_sec;    / seconds (0 - 60) /
int tm_min;    / minutes (0 - 59) /
int tm_hour;   / hours (0 - 23) /
int tm_mday;   / day of month (1 - 31) /
int tm_mon;    / month of year (0 - 11) /
int tm_year;   / year - 1900 /
int tm_wday;   / day of week (Sunday = 0) /
int tm_yday;   / day of year (0 - 365) /
int tm_isdst;  / is summer time in effect? /
char tm_zone;  / abbreviation of timezone name /
long tm_gmtoff; / offset from UTC in seconds /
```

The `tm_zone` and `tm_gmtoff` fields exist, and are filled in, only if arrangements to do so were made when the library containing these functions was created. There is no guarantee that these fields will continue to exist in this form in future releases of this code.

`tm_isdst` is non-zero if summer time is in effect.

`tm_gmtoff` is the offset (in seconds) of the time represented from UTC, with positive values indicating east of the Prime Meridian.

FILES

<code>/usr/local/etc/zoneinfo</code>	Time zone information directory
<code>/usr/local/etc/zoneinfo/localtime</code>	Local time zone file
<code>/usr/local/etc/zoneinfo/posixrules</code>	Used with POSIX-style TZs
<code>/usr/local/etc/zoneinfo/GMT</code>	For UTC leap seconds

If `/usr/local/etc/zoneinfo/GMT` is absent, UTC leap seconds are loaded from `/usr/local/etc/zoneinfo/posixrules`.

SEE ALSO

`getenv(3)`, `newtztset(3)`, `time(2)`, `tzfile(5)`

NOTES

The return values point to static data; the data is overwritten by each call. The `tm_zone` field of a returned `struct tm` points to a static array of characters, which will also be overwritten at the next call (and by calls to `tzset`).

Avoid using out-of-range values with `mktime` when setting up lunch with promptness sticklers in Riyadh.

tzset

`tzset`—Initializes time conversion information

SYNOPSIS

```
void tzset();
cc ... -lz
```

DESCRIPTION

`tzset` uses the value of the environment variable `TZ` to set time conversion information used by `localtime`. If `TZ` does not appear in the environment, the best available approximation to local wall clock time, as specified by the `tzfile(5)`-format file `localtime` in the system time conversion information directory, is used by `localtime`. If `TZ` appears in the environment but its value is a null string, Coordinated Universal Time (UTC) is used (without leap second correction). If `TZ` appears in the environment and its value is not a null string, it is used in one of the following ways:

If the value begins with a colon, it is used as a pathname of a file from which to read the time conversion information.

If the value does not begin with a colon, it is first used as the pathname of a file from which to read the time conversion information, and, if that file cannot be read, is used directly as a specification of the time conversion information.

When `TZ` is used as a pathname, if it begins with a slash, it is used as an absolute pathname; otherwise, it is used as a pathname relative to a system time conversion information directory. The file must be in the format specified in `tzfile(5)`.

When `TZ` is used directly as a specification of the time conversion information, it must have the following syntax (spaces inserted for clarity):

```
std offset[dst[offset][, rule]]
```

The elements are as follows:

<code>std</code> and <code>dst</code>	Three or more bytes that are the designation for the standard (<code>std</code>) or summer (<code>dst</code>) time zone. Only <code>std</code> is required; if <code>dst</code> is missing, then summer time does not apply in this locale. Uppercase and lowercase letters are explicitly allowed. Any characters except a leading colon (:), digits, comma (,), minus (-), plus (+), and ASCII NUL are allowed.
<code>offset</code>	Indicates the value one must add to the local time to arrive at Coordinated Universal Time. The <code>offset</code> has the form: <pre>hh[:mm[:ss]]</pre> <p>The minutes (<code>mm</code>) and seconds (<code>ss</code>) are optional. The hour (<code>hh</code>) is required and may be a single digit. The <code>offset</code> following <code>std</code> is required. If no <code>offset</code> follows <code>dst</code>, summer time is assumed to be one hour ahead of standard time. One or more digits may be used; the value is always interpreted as a decimal number. The hour must be between zero and 24, and the minutes (and seconds)—if present—between zero and 59. If preceded by a "+", the time zone shall be east of the Prime Meridian; otherwise, it shall be west (which may be indicated by an optional preceding "-").</p>
<code>rule</code>	Indicates when to change to and back from summer time. The <code>rule</code> has the form: <pre>date/time,date/time</pre> <p>where the first <code>date</code> describes when the change from standard to summer time occurs and the second <code>date</code> describes when the change back happens. Each <code>time</code> field describes when, in current local time, the change to the other time is made.</p> <p>The format of <code>date</code> is one of the following:</p> <p>The <code>d</code>'th day ($0 \leq d \leq 6$) of week <code>n</code> of month <code>m</code> of the year ($1 \leq n \leq 5$, $1 \leq m \leq 12$, where week 5 means "the last <code>d</code> day in month <code>m</code>" which may occur in either the fourth or the fifth week). Week 1 is the first week in which the <code>d</code>'th day occurs. Day zero is Sunday.</p>
<code>Jn</code>	The Julian day <code>n</code> ($1 \leq n \leq 365$). Leap days are not counted; that is, in all years—including leap years—February 28 is day 59 and March 1 is day 60. It is impossible to explicitly refer to the occasional February 29.

`n` The zero-based Julian day ($0 \leq n \leq 365$). Leap days are counted, and it is possible to refer to February 29.

`Mm.n.d` The d 'th day ($0 \leq d \leq 6$) of week n of month m of the year ($1 \leq n \leq 5$, $1 \leq m \leq 12$, where week 5 means “the last d day in month m ,” which may occur in either the fourth or the fifth week). Week 1 is the first week in which the d 'th day occurs. Day zero is Sunday.

The `time` has the same format as `offset` except that no leading sign (“+” or “-”) is allowed. The default, if `time` is not given, is 02:00:00.

If no `rule` is present in `TZ`, the rules specified by the `tzfile(5)`-format file `posixrules` in the system time conversion information directory are used, with the standard and summer time offsets from UTC replaced by those specified by the `offset` values in `TZ`.

For compatibility with System V Release 3.1, a semicolon (;) may be used to separate the `rule` from the rest of the specification.

If the `TZ` environment variable does not specify a `tzfile(5)`-format and cannot be interpreted as a direct specification, UTC is used.

FILES

<code>/usr/local/etc/zoneinfo</code>	Time zone information directory
<code>/usr/local/etc/zoneinfo/localtime</code>	Local time zone file
<code>/usr/local/etc/zoneinfo/posixrules</code>	Used with POSIX-style <code>TZs</code>
<code>/usr/local/etc/zoneinfo/GMT</code>	For UTC leap seconds

If `/usr/local/etc/zoneinfo/GMT` is absent, UTC leap seconds are loaded from `/usr/local/etc/zoneinfo/posixrules`.

on_exit

`on_exit`—Registers a function to be called at normal program termination

SYNOPSIS

```
#include <stdlib.h>
int on_exit(void (*function)(int , void *), void *arg);
```

DESCRIPTION

The `on_exit()` function registers the given function to be called at normal program termination, whether via `exit(2)` or via return from the program's main. The function is passed the argument to `exit(3)` and the `arg` argument from `on_exit()`.

RETURN VALUE

The `on_exit()` function returns the value 0 if successful; otherwise, the value -1 is returned.

SEE ALSO

`exit(3)`, `atexit(3)`

opendir

`opendir`—Opens a directory

SYNOPSIS

```
#include <sys/types.h>
#include <dirent.h>
DIR *opendir(const char *name);
```

DESCRIPTION

The `opendir()` function opens a directory stream corresponding to the directory name, and returns a pointer to the directory stream. The stream is positioned at the first entry in the directory.

RETURN VALUE

The `opendir()` function returns a pointer to the directory stream or `NULL` if an error occurred.

ERRORS

<code>EACCESS</code>	Permission denied
<code>EMFILE</code>	Too many file descriptors in use by process
<code>ENFILE</code>	Too many files are currently open in the system
<code>ENOENT</code>	Directory does not exist, or <code>name</code> is an empty string
<code>ENOMEM</code>	Insufficient memory to complete the operation
<code>ENOTDIR</code>	<code>name</code> is not a directory

CONFORMS TO

SVID 3, POSIX, BSD 4.3

parsedate

`parsedate`—Converts time and date string to number

SYNOPSIS

```
#include <sys/types.h>
typedef struct _TIMEINFO f
time_t time;
long usec;
long tzone;
} TIMEINFO;
time_t
parsedate(text, now)
char *text;
TIMEINFO *now;
```

DESCRIPTION

`parsedate` converts many common time specifications into the number of seconds since the epoch, that is, a `time_t`; see `time(2)`.

`parsedate` returns the time, or `-1` on error. `text` is a character string containing the time and date. `now` is a pointer to the time that should be used for calculating relative dates. If `now` is `NULL`, then `GetTimeInfo` in `libinn(3)` is used to obtain the current time and time zone.

The character string consists of zero or more specifications of the following form:

<code>time</code>	A time of day, which is of the form <code>hh[:mm[:ss]] [meridi an][zone]</code> or <code>hhmm [meridi an][zone]</code> . If no meridian is specified, <code>hh</code> is interpreted on a 24-hour clock.
<code>date</code>	A specific month and day with optional year. The acceptable formats are <code>mm/dd[/yy]</code> , <code>yyyy/mm/dd</code> , <code>monthname dd[, yy]</code> , <code>dd monthname [yy]</code> , and <code>day,ddmonthnameyy</code> , and <code>day, dd monthname yy</code> . The default year is the current year. If the year is less than 100, then 1900 is added to it; if it is less than 21, then 2000 is added to it.
<code>relative time</code>	A specification relative to the current time. The format is <code>number unit</code> ; acceptable units are <code>year</code> , <code>month</code> , <code>week</code> , <code>day</code> , <code>hour</code> , <code>minute</code> (or <code>min</code>), and <code>second</code> (or <code>sec</code>). The unit can be specified as a singular or plural, as in 3 weeks.

The actual date is calculated according to the following steps. First, any absolute date or time is processed and converted. Using that time as the base, day-of-week specifications are added. Next, relative specifications are used. If a date or day is specified, and no absolute or relative time is given, midnight is used. Finally, a correction is applied so that the correct hour of the day is produced after allowing for Daylight Savings Time differences.

`parsedate` ignores case when parsing all words; unknown words are taken to be unknown time zones, which are treated as GMT. The names of the months and days of the week can be abbreviated to their first three letters, with optional trailing period. Periods are ignored in any time zone or meridian values.

BUGS

`parsedate` does not accept all desirable and unambiguous constructions. Semantically incorrect dates such as “February 31” are accepted.

Daylight Savings Time is always taken as a one-hour change that is wrong for some places. The Daylight Savings Time correction can get confused if parsing a time within an hour of when the reckoning changes, or if given a partial date.

HISTORY

Originally written by Steven M. Bellovin (smb@research.att.com) while at the University of North Carolina at Chapel Hill and distributed under the name `getdate`.

A major overhaul was done by Rich Salz (rsalz@bbn.com) and Jim Berets (jberets@bbn.com) in August, 1990.

It was further revised (primarily to remove obsolete constructs and time zone names) a year later by Rich (now rsalz@osf.org) for InterNetNews, and the name was changed.

perror

`perror`—Prints a system error message

SYNOPSIS

```
#include <stdio.h>

void perror(const char *s);

#include <errno.h>
```

```
const char *sys_errlist[];
int sys_nerr;
```

DESCRIPTION

The routine `perror()` produces a message on the standard error output, describing the last error encountered during a call to a system or library function. The argument string `s` is printed first, then a colon and a blank, then the message and a newline. To be of most use, the argument string should include the name of the function that incurred the error. The error number is taken from the external variable `errno`, which is set when errors occur but not cleared when nonerroneous calls are made.

The global error list `sys_errlist[]` indexed by `errno` can be used to obtain the error message without the newline. The largest message number provided in the table is `sys_nerr - 1`. Be careful when directly accessing this list because new error values may not have been added to `sys_errlist[]`.

When a system call fails, it usually returns `-1` and sets the variable `errno` to a value describing what went wrong. (These values can be found in `<errno.h>`.) Many library functions do likewise. The function `perror()` serves to translate this error code into human-readable form. Note that `errno` is undefined after a successful library call. This call may well change this variable, even though it succeeds, for example, because it internally used some other library function that failed. Thus, if a failing call is not immediately followed by a call to `perror`, the value of `errno` should be saved.

popen, pclose

popen, pclose—Process I/O

SYNOPSIS

```
#include <stdio.h>

FILE *popen(const char *command, const char *type);

int pclose(FILE *stream);
```

DESCRIPTION

The `popen()` function opens a process by creating a pipe, forking, and invoking the shell. Because a pipe is by definition unidirectional, the `type` argument may specify only reading or writing, not both; the resulting stream is correspondingly read-only or write-only.

The `command` argument is a pointer to a null-terminated string containing a shell command line. This command is passed to `/bin/sh` using the `-c` flag; interpretation, if any, is performed by the shell. The `mode` argument is a pointer to a null-terminated string which must be either `r` for reading or `w` for writing.

The return value from `popen()` is a normal standard I/O stream in all respects save that it must be closed with `pclose()` rather than `fclose()`. Writing to such a stream writes to the standard input of the command; the command's standard output is the same as that of the process that called `popen()`, unless this is altered by the command itself. Conversely, reading from a "popened" stream reads the command's standard output, and the command's standard input is the same as that of the process that called `popen`.

Note that output `popen` streams are fully buffered by default.

The `pclose` function waits for the associated process to terminate and returns the exit status of the command as returned by `wait4`.

RETURN VALUE

The `popen` function returns `NULL` if the `fork(2)` or `pipe(2)` calls fail, or if it cannot allocate memory.

The `pclose` function returns `-1` if `stream` is not associated with a “popened” command, if `stream` already “pclosed,” or if `wait4` returns an error.

ERRORS

The `popen` function does not reliably set `errno`. (Is this true for Linux?)

BUGS

The standard input of a command opened for reading shares its seek offset with the process that called `popen()`; therefore, if the original process has done a buffered read, the command’s input position may not be as expected. Similarly, the output from a command opened for writing may become intermingled with that of the original process. The latter can be avoided by calling `fflush(3)` before `popen`.

Failure to execute the shell is indistinguishable from the shell’s failure to execute `command`, or an immediate exit of the command. The only hint is an exit status of 127. (Is this true under Linux?)

The function `popen()` always calls `sh`, never calls `csh`.

HISTORY

A `popen()` and a `pclose()` function appeared in Version 7 AT&T UNIX.

printf, fprintf, sprintf, snprintf, vprintf, vfprintf, vsprintf, vsnprintf

`printf`, `fprintf`, `sprintf`, `snprintf`, `vprintf`, `vfprintf`, `vsprintf`, `vsnprintf`—Formatted output conversion

SYNOPSIS

```
#include <stdio.h>

int printf( const char *format, ...);
int fprintf( FILE *stream, const char *format, ...);
int sprintf( char *str, const char *format, ...);
int snprintf( char *str, size_t size, const char *format, ...);

#include <stdarg.h>

int vprintf( const char *format, va_list ap);
int vfprintf( FILE *stream, const char *format, va_list ap);
int vsprintf( char *str, const char *format, va_list ap);
int vsnprintf( char *str, size_t size, const char *format, va_list ap);
```

DESCRIPTION

The `printf` family of functions produces output according to a `format`, as described in the following paragraphs. The functions `printf` and `vprintf` write output to `stdout`, the standard output stream; `fprintf` and `vfprintf` write output to the given output stream; `sprintf`, `snprintf`, `vsprintf`, and `vsnprintf` write to the character string `str`.

These functions write the output under the control of a `format` string that specifies how subsequent arguments (or arguments accessed via the variable-length argument facilities of `stdarg(3)`) are converted for output.

These functions return the number of characters printed (not including the trailing `\0` used to end output to strings). `snprintf` and `vsnprintf` do not write more than `size` bytes (including the trailing `\0`), and return `-1` if the output was truncated due to this limit.

The `format` string is composed of zero or more directives: ordinary characters (not `%`), which are copied unchanged to the output stream; and conversion specifications, each of which results in fetching zero or more subsequent arguments. Each conversion specification is introduced by the character `%`. The arguments must correspond properly (after type promotion) with the conversion specifier. After the `%`, zero or more of the following flags appear in sequence:

- # Specifying that the value should be converted to an alternate form. For `c`, `d`, `i`, `n`, `p`, `s`, and `u` conversions, this option has no effect. For `o` conversions, the precision of the number is increased to force the first character of the output string to a zero (except if a zero value is printed with an explicit precision of zero). For `x` and `X` conversions, a non-zero result has the string `0x` (or `0X` for `X` conversions) prepended to it. For `e`, `E`, `f`, `g`, and `G` conversions, the result will always contain a decimal point, even if no digits follow it (normally, a decimal point appears in the results of those conversions only if a digit follows). For `g` and `G` conversions, trailing zeros are not removed from the result as they would otherwise be.
 - 0 Specifying zero padding. For all conversions except `n`, the converted value is padded on the left with zeros rather than blanks. If a precision is given with a numeric conversion (`d`, `i`, `o`, `u`, `i`, `x`, and `X`), the `0` flag is ignored.
 - (a negative field width flag) Indicates the converted value is to be left adjusted on the field boundary. Except for `n` conversions, the converted value is padded on the right with blanks, rather than on the left with blanks or zeros. `A -` overrides a `0` if both are given.
 - ' ' (a space) Specifying that a blank should be left before a positive number produced by a signed conversion (`d`, `e`, `E`, `f`, `g`, `G`, or `i`).
 - + Specifying that a sign always be placed before a number produced by a signed conversion. `A +` overrides a space if both are used.
 - ' ' Specifying that in a numerical argument the output is to be grouped if the locale information indicates any. Note that many versions of `gcc` cannot parse this option and will issue a warning.
- An optional decimal digit string specifying a minimum field width. If the converted value has fewer characters than the field width, it will be padded with spaces on the left (or right, if the left-adjustment flag has been given) to fill out the field width.
- An optional precision, in the form of a period (`.`) followed by an optional digit string. If the digit string is omitted, the precision is taken as zero. This gives the minimum number of digits to appear for `d`, `i`, `o`, `u`, `x`, and `X` conversions; the number of digits to appear after the decimal point for `e`, `E`, and `f` conversions; the maximum number of significant digits for `g` and `G` conversions; or the maximum number of characters to be printed from a string for `s` conversions.
- The optional character `h`, specifying that a following `d`, `i`, `o`, `u`, `x`, or `X` conversion corresponds to a `short int` or `unsigned short int` argument, or that a following `n` conversion corresponds to a pointer to a `short int` argument.
- The optional character `l` (ell) specifying that a following `d`, `i`, `o`, `u`, `x`, or `X` conversion applies to a pointer to a `long int` or `unsigned long int` argument, or that a following `n` conversion corresponds to a pointer to a `long int` argument. Linux provides a non-ANSI-compliant use of two `l` flags as a synonym to `q` or `L`. Thus, `ll` can be used in combination with float conversions. This usage is, however, strongly discouraged.

The character `L` specifying that a following `e`, `E`, `f`, `g`, or `G` conversion corresponds to a `long double` argument, or a following `d`, `i`, `o`, `u`, `x`, or `X` conversion corresponds to a `long long` argument. Note that `long long` is not specified in ANSI C and therefore not portable to all architectures.

The optional character `q`. This is equivalent to `L`. See the “Standards” and “Bugs” sections for comments on the use of `ll`, `L`, and `q`.

A `z` character specifying that the following integer (`d`, `i`, `o`, `u`, `i`, `x`, and `X`) conversion corresponds to a `size_t` argument.

A character that specifies the type of conversion to be applied.

A field width or precision, or both, may be indicated by an asterisk `*` instead of a digit string. In this case, an `int` argument supplies the field width or precision. A negative field width is treated as a left adjustment flag followed by a positive field width; a negative precision is treated as though it were missing.

The conversion specifiers and their meanings are as follows:

<code>diouxX</code>	The <code>int</code> (or appropriate variant) argument is converted to signed decimal (<code>d</code> and <code>i</code>), unsigned octal (<code>o</code>), unsigned decimal (<code>u</code>), or unsigned hexadecimal (<code>x</code> and <code>X</code>) notation. The letters <code>abcdef</code> are used for <code>x</code> conversions; the letters <code>ABCDEF</code> are used for <code>X</code> conversions. The precision, if any, gives the minimum number of digits that must appear; if the converted value requires fewer digits, it is padded on the left with zeros.
<code>eE</code>	The <code>double</code> argument is rounded and converted in the style <code>[-]d.ddde\dd</code> where there is one digit before the decimal-point character and the number of digits after it is equal to the precision; if the precision is missing, it is taken as 6; if the precision is zero, no decimal-point character appears. An <code>E</code> conversion uses the letter <code>E</code> (rather than <code>e</code>) to introduce the exponent. The exponent always contains at least two digits; if the value is zero, the exponent is <code>00</code> .
<code>f</code>	The <code>double</code> argument is rounded and converted to decimal notation in the style <code>[-].ddd.ddd</code> , where the number of digits after the decimal-point character is equal to the precision specification. If the precision is missing, it is taken as 6; if the precision is explicitly zero, no decimal-point character appears. If a decimal point appears, at least one digit appears before it.
<code>g</code>	The <code>double</code> argument is converted in style <code>f</code> or <code>e</code> (or <code>E</code> for <code>G</code> conversions). The precision specifies the number of significant digits. If the precision is missing, 6 digits are given; if the precision is zero, it is treated as 1. Style <code>e</code> is used if the exponent from its conversion is less than negative 4 or greater than or equal to the precision. Trailing zeros are removed from the fractional part of the result; a decimal point appears only if it is followed by at least one digit.
<code>c</code>	The <code>int</code> argument is converted to an unsigned <code>char</code> , and the resulting character is written.
<code>s</code>	The <code>char *</code> argument is expected to be a pointer to an array of character type (pointer to a string). Characters from the array are written up to (but not including) a terminating <code>NUL</code> character; if a precision is specified, no more than the number specified are written. If a precision is given, no null character need be present; if the precision is not specified, or is greater than the size of the array, the array must contain a terminating <code>NUL</code> character.
<code>p</code>	The <code>void *</code> pointer argument is printed in hexadecimal (as if by <code>%#x</code> or <code>%#lx</code>).
<code>n</code>	The number of characters written so far is stored into the integer indicated by the <code>int *</code> (or variant) pointer argument. No argument is converted.
<code>%</code>	A <code>%</code> is written. No argument is converted. The complete conversion specification is <code>%%</code> .

In no case does a nonexistent or small field width cause truncation of a field; if the result of a conversion is wider than the field width, the field is expanded to contain the conversion result.

EXAMPLES

To print a date and time in the form “Sunday, July 3, 10:02,” where `weekday` and `month` are pointers to strings:

```
#include <stdio.h>
fprintf(stdout, "%s, %s %d, %.2d:%.2d\n",
weekday, month, day, hour, min);
```

To print to five decimal places:

```
#include <math.h>
#include <stdio.h>
fprintf(stdout, "pi = %.5f\n", 4 * atan(1.0));
```

To allocate a 128-byte string and print into it:

```
#include <stdio.h>
#include <stdlib.h>
#include <stdarg.h>

char *newfmt(const char *fmt, ...)
{
    char *p;
    va_list ap;
    if ((p = malloc(128)) == NULL)
        return (NULL);
    va_start(ap, fmt);
    (void) vsnprintf(p, 128, fmt, ap);
    va_end(ap);
    return (p);
}
```

SEE ALSO

`printf(1)`, `scanf(3)`

STANDARDS

The `fprintf`, `printf`, `sprintf`, `vprintf`, `vfprintf`, and `vsprintf` functions conform to ANSI C3.159-1989 (“ANSI C”).

The `q` flag is the BSD 4.4 notation for `long long`, while `ll` or the usage of `L` in integer conversions is the GNU notation.

The Linux version of these functions is based on the GNU `libc` library. Take a look at the `info` documentation of GNU `libc` (`glibc-1.08`) for a more concise description.

BUGS

Some floating point conversions under Linux cause memory leaks.

All functions are fully ANSI C3.159-1989 conformant, but provide the additional flags `q`, `z`, and `'` as well as an additional behavior of the `L` and `l` flags. The latter may be considered to be a bug, as it changes the behavior of flags defined in ANSI C3.159-1989.

The effect of padding the `%p` format with zeros (either by the `0` flag or by specifying a precision), and the benign effect (that is, none) of the `#` flag on `%n` and `%p` conversions, as well as nonsensical combinations that are not standard; such combinations should be avoided.

Some combinations of flags defined by ANSI C are not making sense (for example, `%Ld`). While they may have a well-defined behavior on Linux, this need not to be so on other architectures. Therefore, it usually is better not to use flags that are not defined by ANSI C at all; in other words, that use `q` instead of `L` in combination with `diouxX` conversions or `ll`.

The usage of `q` is not the same as on BSD 4.4, as it may be used in float conversions equivalently to `L`.

Because `printf` and `vprintf` assume an infinitely long string, callers must be careful not to overflow the actual space; this is often impossible to assure.

Linux man page, 28 January 1996

psignal

`psignal`—Prints signal message

SYNOPSIS

```
#include <signal.h>
void psignal(int sig, const char *s);
extern const char *const sys_siglist[]
```

DESCRIPTION

The `psignal()` function displays a message on `stderr` consisting of the string `s`, a colon, a space, and a string describing the signal number `sig`. If `sig` is invalid, the message displayed will indicate an unknown signal.

The array `sys_siglist` holds the signal description strings indexed by signal number.

RETURN VALUE

The `psignal()` function returns no value.

CONFORMS TO

BSD 4.3

SEE ALSO

`perror(3)`, `strsignal(3)`

GNU, 13 April 1993

putenv

`putenv`—Changes or adds an environment variable

SYNOPSIS

```
#include <stdlib.h>
int putenv(const char *string);
```

DESCRIPTION

The `putenv()` function adds or changes the value of environment variables. The argument `string` is of the form `name = value`. If `name` does not already exist in the environment, then `string` is added to the environment. If `name` does exist, then the value of `name` in the environment is changed to `value`.

RETURN VALUE

The `putenv()` function returns zero on success, or `-1` if an error occurs.

ERRORS

`ENOMEM`

Insufficient space to allocate new environment

CONFORMS TO

SVID 3, POSIX, BSD 4.3

SEE ALSO

getenv(3), setenv(3), unsetenv(3)

GNU, 8 April 1993

putpwent

putpwent—Writes a password file entry

SYNOPSIS

```
#include <pwd.h>
#include <stdio.h>
#include <sys/types.h>
int putpwent(const struct passwd *p, FILE *stream);
```

DESCRIPTION

The `putpwent()` function writes a password entry from the structure `p` in the file associated with `stream`.

The `passwd` structure is defined in `<pwd.h>` as follows:

```
struct passwd {
    char    *pw_name;        /* user name */
    char    *pw_passwd;     /* user password */
    uid_t   pw_uid;         /* user id */
    gid_t   pw_gid;         /* group id */
    char    *pw_gecos;      /* real name */
    char    *pw_dir;        /* home directory */
    char    *pw_shell;      /* shell program */
};
```

RETURN VALUE

The `putpwent()` function returns 0 on success, or -1 if an error occurs.

ERRORS

EINVAL Invalid (NULL) argument given

CONFORMS TO

SVID 3

fputc, fputs, putc, putchar, puts

fputc, fputs, putc, putchar, puts—Output of characters and strings

SYNOPSIS

```
#include <stdio.h>
int fputc(int c,FILE*stream);
int fputs(const char *s,FILE*stream);
int putc(int c,FILE *stream);
int putchar(int c);
int puts(char *s);
int ungetc(int c,FILE *stream);
```

DESCRIPTION

`fputc()` writes the character `c`, cast to an unsigned `char`, to `stream`.

`fputs()` writes the string `s` to `stream`, without its trailing `\0`.

`putc()` is equivalent to `fputc()` except that it may be implemented as a macro that evaluates `stream` more than once.

`putchar(c)`; is equivalent to `putc(c,stdout)`.

`puts()` writes the string `s` and a trailing newline to `stdout`.

Calls to the functions described here can be mixed with each other and with calls to other output functions from the `stdio` library for the same output stream.

RETURN VALUES

`fputc()`, `putc()`, and `putchar()` return the character written as an unsigned `char` cast to an `int` or `EOF` on error.

`puts()` and `fputs()` return a non-negative number on success, or `EOF` on error.

CONFORMS TO

ANSI C, POSIX.1

BUGS

It is not advisable to mix calls to output functions from the `stdio` library with low-level calls to `write()` for the file descriptor associated with the same output stream; the results will be undefined and very probably not what you want.

qio

`qio`—Quick I/O part of InterNetNews library

SYNOPSIS

```
#include "qio.h"
QIOSTATE *
QIOOpen(name, size)
char *name;
int size;
QIOSTATE * QIOfdopen(fd, size)
int fd;
int size;
void QIOclose(qp)
QIOSTATE *qp;
```

```

char * QIOread(qp)
QIOSTATE *qp;
int QIOlength(qp)
QIOSTATE *qp;
int QIOtoolong(qp)
QIOSTATE *qp;
int QIOerror(qp)
QIOSTATE *qp;
int QIOtell(qp)
QIOSTATE *qp;
int QIOrewind(qp)
QIOSTATE *qp;
int QIOfileno(qp)
QIOSTATE *qp;

```

DESCRIPTION

The routines described in this manual page are part of the InterNetNews library, `libinn(3)`. They are used to provide quick read access to files. The letters `QIO` stand for Quick I/O.

`QIOopen` opens the file `name` for reading. It uses a buffer of `size` bytes, which must also be larger than the longest expected line. The header file defines the constant `QIO_BUFFER` as a reasonable default. If `size` is zero, then `QIOopen` will call `stat(2)` and use the returned block size; if that fails it will use `QIO_BUFFER`. It returns `NULL` on error, or a pointer to a handle to be used in other calls. `QIOfdopen` performs the same function except that `fd` refers to an already-open descriptor.

`QIOclose` closes the open file and releases any resources used by it.

`QIOread` returns a pointer to the next line in the file. The trailing newline will be replaced with a `\0`. If EOF is reached, an error occurs, or if the line is longer than the buffer, `QIOread` returns `NULL`.

After a successful call to `QIOread`, `QIOlength` will return the length of the current line.

The functions `QIOtoolong` and `QIOerror` can be called after `QIOread` returns `NULL` to determine if there was an error, or if the line was too long. If `QIOtoolong` returns non-zero, then the current line did not fit in the buffer, and the next call to `QIOread` will try read the rest of the line. Long lines can only be discarded. If `QIOerror` returns non-zero, then a serious I/O error occurred.

`QIOtell` returns the `lseek(2)` offset at which the next line will start.

`QIOrewind` sets the read pointer back to the beginning of the file.

`QIOfileno` returns the descriptor of the open file.

`QIOlength`, `QIOtoolong`, `QIOerror`, `QIOtell`, and `QIOfileno` are implemented as macros defined in the header file.

EXAMPLE

```

QIOSTATE *h;
long offset;
char *p;
h = QIOopen("/etc/motd", QIO_BUFFER);
for (offset = QIOtell(h); (p = QIOread(h)) != NULL; offset = QIOtell(h))
printf("At %ld, %s\n", offset, p);
if (QIOerror(h)) {
    perror("Read error");
    exit(1);
}
QIOclose(h);

```

HISTORY

Written by Rich Salz (`rsalz@uunet.uu.net`) for InterNetNews.

qsort

`qsort`—Sorts an array

SYNOPSIS

```
#include <stdlib.h>
void qsort(void *base, size_t nmem, size_t size, int(*compar)
(const void *, const void *));
```

DESCRIPTION

The `qsort()` function sorts an array with `nmem` elements of size `size`. The base argument points to the start of the array.

The contents of the array are sorted in ascending order according to a comparison function pointed to by `compar`, which is called with two arguments that point to the objects being compared.

The comparison function must return an integer less than, equal to, or greater than zero if the first argument is considered to be respectively less than, equal to, or greater than the second. If two members compare as equal, their order in the sorted array is undefined.

RETURN VALUE

The `qsort()` function returns no value.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

`sort(1)`

GNU, 29 March 1993

raise

`raise`—Sends a signal to the current process

SYNOPSIS

```
#include <signal.h>
int raise (int sig);
```

DESCRIPTION

The `raise` function sends a signal to the current process. It is equivalent to

```
kill(getpid(), sig)
```

RETURN VALUE

Zero on success, non-zero for failure.

CONFORMS TO

ANSI C

GNU, 31 August 1995

rand, srand

rand, srand—Random number generator

SYNOPSIS

```
#include <stdlib.h>
int rand(void);
void srand(unsigned int seed);
```

DESCRIPTION

The `rand()` function returns a pseudo-random integer between 0 and `RAND_MAX`.

The `srand()` function sets its argument as the seed for a new sequence of pseudo-random integers to be returned by `rand()`. These sequences are repeatable by calling `srand()` with the same seed value.

If no seed value is provided, the `rand()` function is automatically seeded with a value of 1.

RETURN VALUE

The `rand()` function returns a value between 0 and `RAND_MAX`. The `srand()` returns no value.

NOTES

The versions of `rand()` and `srand()` in the Linux C Library use the same random number generator as `random()` and `srandom()`, so the lower-order bits should be as random as the higher-order bits. However, on older `rand()` implementations, the lower-order bits are much less random than the higher-order bits.

In *Numerical Recipes in C: The Art of Scientific Computing* (William H. Press, Brian P. Flannery, Saul A. Teukolsky, William T. Vetterling; New York: Cambridge University Press, 1990, first ed, p. 207), the following comments are made:

“If you want to generate a random integer between 1 and 10, you should always do it by

```
j=1+(int) (10.0*rand()/(RAND+MAX+1.0));
```

and never by anything resembling

```
j=1+((int) (1000000.0*rand()) % 10);
```

(which uses lower-order bits).”

Random-number generation is a complex topic. The *Numerical Recipes in C* book (see preceding reference) provides an excellent discussion of practical random-number generation issues in Chapter 7, “Random Numbers.”

For a more theoretical discussion that also covers many practical issues in depth, please see Chapter 3, “Random Numbers,” in Donald E. Knuth’s *The Art of Computer Programming, Volume 2* (Seminumerical Algorithms), 2nd ed.; Reading, Massachusetts: Addison-Wesley Publishing Company, 1981.

random, srandom, initstate, setstate

random, srandom, initstate, setstate—Random number generator

SYNOPSIS

```
#include <stdlib.h>
long int random(void);
void srand(unsigned int seed);
char *initstate(unsigned int seed, char *state,int n);
char *setstate(char *state);
```

DESCRIPTION

The `random()` function uses a nonlinear additive feedback random number generator employing a default table of size 31 long integers to return successive pseudo-random numbers in the range from 0 to `RAND_MAX`. The period of this random number generator is very large, approximately $16 * ((2^{**31}) - 1)$.

The `srand()` function sets its argument as the seed for a new sequence of pseudo-random integers to be returned by `random()`. These sequences are repeatable by calling `srand()` with the same seed value. If no seed value is provided, the `random()` function is automatically seeded with a value of 1.

The `initstate()` function allows a state array `state` to be initialized for use by `random()`. The size of the state array `n` is used by `initstate()` to decide how sophisticated a random number generator it should use—the larger the state array, the better the random numbers will be. `seed` is the seed for the initialization, which specifies a starting point for the random number sequence, and provides for restarting at the same point.

The `setstate()` function changes the state array used by the `random()` function. The state array `state` is used for random number generation until the next call to `initstate()` or `setstate()`. `state` must first have been initialized using `initstate()`.

RETURN VALUE

The `random()` function returns a value between 0 and `RAND_MAX`. The `srand()` function returns no value. The `initstate()` and `setstate()` functions return a pointer to the previous state array.

ERRORS

`EINVAL` A state array of less than 8 bytes was specified to `initstate()`.

NOTES

Current “optimal” values for the size of the state array `n` are 8, 32, 64, 128, and 256 bytes; other amounts will be rounded down to the nearest known amount. Using less than 8 bytes will cause an error.

CONFORMS TO

BSD 4.3

readdir

`readdir`—Reads a directory

SYNOPSIS

```
#include <sys/types.h>
#include <dirent.h>
struct dirent *readdir(DIR *dir);
```

DESCRIPTION

The `readdir()` function returns a pointer to a `dirent` structure representing the next directory entry in the directory stream pointed to by `dir`. It returns `NULL` on reaching the end-of-file or if an error occurred.

The data returned by `readdir()` is overwritten by subsequent calls to `readdir()` for the same directory stream.

According to POSIX, the `dirent` structure contains a field `char_d_name[]` of unspecified size, with at most `NAME_MAX` characters preceding the terminating null character. Use of other fields will harm the portability of your programs.

RETURN VALUE

The `readdir()` function returns a pointer to a `dirent` structure, or `NULL` if an error occurs or end-of-file is reached.

ERRORS

`EBADF` Invalid directory stream descriptor `dir`

CONFORMS TO

readv, writev

`readv, writev`—Reads or writes data into multiple buffers

SYNOPSIS

```
#include <sys/uio.h>
int readv(int filedes, const struct iovec *vector,
size_t count);
int writev(int filedes, const struct iovec *vector,
size_t count);
```

DESCRIPTION

The `readv()` function reads `count` blocks from the file associated with the file descriptor `filedes` into the multiple buffers described by `vector`.

The `writev()` function writes at most `count` blocks described by `vector` to the file associated with the file descriptor `filedes`.

The pointer `vector` points to a `struct iovec` defined in `<sys/uio.h>` as

```
struct iovec
{
void *iovbase; /* Starting address */
size_t iov_len; /* Number of bytes */
};
```

Buffers are processed in the order `vector[0]`, `vector[1]`, ... `vector[count]`.

The `readv()` function works just like `read(2)` except that multiple buffers are filled.

The `writev()` function works just like `write(2)` except that multiple buffers are written out.

RETURN VALUES

The `readv()` function returns the number of bytes or `-1` on error; the `writev()` function returns the number of bytes written.

ERRORS

The `readv()` and `writev()` functions can fail and set `errno` to the following values:

<code>EBADF</code>	<code>fd</code> is not a valid file descriptor.
<code>EINVAL</code>	<code>fd</code> is unsuitable for reading (for <code>readv()</code>) or writing (for <code>writev()</code>).
<code>EFAULT</code>	<code>buf</code> is outside the processes' address space.
<code>EAGAIN</code>	Nonblocking I/O had been selected in the <code>open()</code> call, and reading or writing could not be done immediately.
<code>EINTR</code>	Reading or writing was interrupted before any data was transferred.

CONFORMS TO

unknown

BUGS

It is not advisable to mix calls to functions like `readv()` or `writev()`, which operate on file descriptors, with the functions from the `stdio` library; the results will be undefined and probably not what you want.

SEE ALSO

`read(2)`, `write(2)`

realpath

`realpath`—Returns the canonicalized absolute pathname.

SYNOPSIS

```
#include <sys/param.h>
#include <unistd.h>
char *realpath(char *path, char resolved_path[]);
```

DESCRIPTION

`realpath` expands all symbolic links and resolves references to `./`, `../` and extra `/` characters in the null-terminated string named by `path` and stores the canonicalized absolute pathname in the buffer of size `MAXPATHLEN` named by `resolved_path`. The resulting path will have no symbolic link, `./`, or `../` components.

RETURN VALUE

If there is no error, it returns a pointer to the `resolved_path`.

Otherwise, it returns a `NULL` pointer and places in `resolved_path` the absolute pathname of the `path` component that could not be resolved. The global variable `errno` is set to indicate the error.

ERRORS

<code>ENOTDIR</code>	A component of the path prefix is not a directory.
<code>EINVAL</code>	The pathname contains a character with the high-order bit set.
<code>ENAMETOOLONG</code>	A component of a pathname exceeded <code>MAXNAMLEN</code> characters, or an entire path name exceeded <code>MAXPATHLEN</code> characters.
<code>ENOENT</code>	The named file does not exist.
<code>EACCES</code>	Search permission is denied for a component of the path prefix.
<code>ELOOP</code>	Too many symbolic links were encountered in translating the pathname.
<code>EIO</code>	An I/O error occurred while reading from the filesystem.

Re_comp, re_exec

re_comp, re_exec—BSD regex functions

SYNOPSIS

```
#include <regex.h>
char *re_comp(char *regex);
int re_exec(char *string);
```

DESCRIPTION

re_comp is used to compile the null-terminated regular expression pointed to by *regex*. The compiled pattern occupies a static area, the pattern buffer, which is overwritten by subsequent use of *re_comp*. If *regex* is NULL, no operation is performed and the pattern buffer's contents are not altered.

re_exec is used to assess whether the null-terminated string pointed to by *string* matches the previously compiled *regex*.

RETURN VALUE

re_comp returns NULL on successful compilation of *regex*; otherwise, it returns a pointer to an appropriate error message.

re_exec returns 1 for a successful match, zero for failure.

CONFORMS TO

BSD 4.3

regex(7), GNU regex manual

Linux, 14 July 1995

regcomp, regex, regerror, regfree

regcomp, regex, regerror, regfree—POSIX regex functions

SYNOPSIS

```
#include <regex.h>
int regcomp(regex_t *preg, const char *regex, int cflags);
int regex(const regex_t *preg, const char *string, size_t nmatch, regmatch_t pmatch[], int eflags);
size_t regerror(int errcode, const regex_t *preg, char *errbuf, size_t errbuf_size);
void regfree(regex_t *preg);
```

POSIX REGEX COMPILING

regcomp is used to compile a regular expression into a form that is suitable for subsequent *regex* searches.

regcomp is supplied with *preg*, a pointer to a pattern buffer storage area; *regex*, a pointer to the null-terminated string; and *cflags*, flags used to determine the type of compilation. All regular expression searching must be done via a compiled pattern buffer; thus, *regex* must always be supplied with the address of a *regcomp* initialized pattern buffer.

`eflags` may be the bitwise or of one or more of the following:

<code>REG_EXTENDED</code>	Use POSIX extended regular expression syntax when interpreting <code>regex</code> . If not set, POSIX basic regular expression syntax is used.
<code>REG_ICASE</code>	Do not differentiate case. Subsequent <code>regex</code> searches using this pattern buffer will be case-insensitive.
<code>REG_NOSUB</code>	Support for substring addressing of matches is not required. The <code>nmatch</code> and <code>pmatch</code> parameters to <code>regex</code> are ignored if the pattern buffer supplied was compiled with this flag set.
<code>REG_NEWLINE</code>	Match-any-character operators don't match a newline. A nonmatching list (<code>[^...]</code>) not containing a newline matches a newline. Match-beginning-of-line operator (<code>^</code>) matches the empty string immediately after a newline, regardless of whether <code>eflags</code> , the execution flags of <code>regex</code> , contains <code>REG_NOTBOL</code> . Match-end-of-line operator (<code>\$</code>) matches the empty string immediately before a newline, regardless of whether <code>eflags</code> contains <code>REG_NOTEOL</code> .

POSIX REGEX MATCHING

`regex` is used to match a null-terminated string against the precompiled pattern buffer, `preg`. `nmatch` and `pmatch` are used to provide information regarding the location of any matches. `eflags` may be the bitwise or of one or both of `REG_NOTBOL` and `REG_NOTEOL`, which cause changes in matching behavior described in the following list.

<code>REG_NOTBOL</code>	The match-beginning-of-line operator always fails to match (but see the compilation flag <code>REG_NEWLINE</code> , in the preceding subsection). This flag may be used when different portions of a string are passed to <code>regex</code> and the beginning of the string should not be interpreted as the beginning of the line.
<code>REG_NOTEOL</code>	The match-end-of-line operator always fails to match (but see the compilation flag <code>REG_NEWLINE</code> , in the preceding subsection).

BYTE OFFSETS

Unless `REG_NOSUB` was set for the compilation of the pattern buffer, it is possible to obtain substring match addressing information. `pmatch` must be dimensioned to have at least `nmatch` elements. These are filled in by `regex` with substring match addresses. Any unused structure elements will contain the value `-1`.

The `regmatch_t` structure that is the type of `pmatch` is defined in `regex.h`:

```
typedef struct
{
    regoff_t rm_so;
    regoff_t rm_eo;
} regmatch_t;
```

Each `rm_so` element that is not `-1` indicates the start offset of the next largest substring match within the string. The relative `rm_eo` element indicates the end offset of the match.

POSIX ERROR REPORTING

`regerror` is used to turn the error codes that can be returned by both `regcomp` and `regex` into error message strings.

`regerror` is passed the error code, `errcode`; the pattern buffer, `preg`; a pointer to a character string buffer, `errbuf`; and the size of the string buffer, `errbuf_size`. It returns the size of the `errbuf` required to contain the null-terminated error message string. If both `errbuf` and `errbuf_size` are non-zero, `errbuf` is filled in with the first `errbuf_size - 1` characters of the error message and a terminating null.

POSIX PATTERN BUFFER FREEING

Supplying `regfree` with a precompiled pattern buffer, `preg` will free the memory allocated to the pattern buffer by the compiling process, `regcomp`.

RETURN VALUE

`regcomp` returns zero for a successful compilation or an error code for failure.

`regexexec` returns zero for a successful match or `REG_NOMATCH` for failure.

ERRORS

The following errors can be returned by `regcomp`:

<code>REG_BADRPT</code>	Invalid use of repetition operators, such as using <code>*</code> as the first character
<code>REG_BADBR</code>	Invalid use of back reference operator
<code>REG_EBRACE</code>	Unmatched brace interval operators
<code>REG_EBRACK</code>	Unmatched bracket list operators
<code>REG_ERANGE</code>	Invalid use of the range operator; for example, the ending point of the range occurs prior to the starting point
<code>REG_ECTYPE</code>	Unknown character class name
<code>REG_EPAREN</code>	Unmatched parenthesis group operators
<code>REG_ESUBREG</code>	Invalid back reference to a subexpression
<code>REG_EEND</code>	Non-specific error
<code>REG_ESCAPE</code>	Invalid escape sequence
<code>REG_BADPAT</code>	Invalid use of pattern operators such as <code>group</code> or <code>list</code>
<code>REG_ESIZE</code>	Compiled regular expression requires a pattern buffer larger than 64Kb
<code>REG_ESPACE</code>	The <code>regex</code> routines ran out of memory

remove

`remove`—Deletes a name and possibly the file to which it refers

SYNOPSIS

```
#include <stdio.h>
int remove(const char *pathname);
```

DESCRIPTION

`remove` deletes a name from the filesystem. If that name was the last link to a file and no processes have the file open, the file is deleted and the space it was using is made available for reuse.

If the name was the last link to a file but any processes still have the file open, the file will remain in existence until the last file descriptor referring to it is closed.

If the name referred to a symbolic link, the link is removed.

If the name referred to a socket, fifo, or device, the name for it is removed, but processes that have the object open may continue to use it.

RETURN VALUE

On success, zero is returned. On error, -1 is returned, and `errno` is set appropriately.

ERRORS

EFAULT	<code>pathname</code> points outside your accessible address space.
EACCES	Write access to the directory containing <code>pathname</code> is not allowed for the process's effective <code>uid</code> , or one of the directories in <code>pathname</code> did not allow search (execute) permission.
EPERM	The directory containing <code>pathname</code> has the sticky-bit (<code>S_ISVTX</code>) set and the process's effective <code>uid</code> is neither the <code>uid</code> of the file to be deleted nor that of the directory containing it.
ENAMETOOLONG	<code>pathname</code> was too long.
ENOENT	A directory component in <code>pathname</code> does not exist or is a dangling symbolic link.
ENOTDIR	A component used as a directory in <code>pathname</code> is not, in fact, a directory.
EISDIR	<code>pathname</code> refers to a directory.
ENOMEM	Insufficient kernel memory was available.
EROFS	<code>pathname</code> refers to a file on a read-only filesystem.

```

DESCRIPTION

These routines are used for making, sending and interpreting query and reply messages with Internet domain name servers.

Global configuration and state information that is used by the resolver routines is kept in the structure `_res`. Most of the values have reasonable defaults and can be ignored. Options stored in `_res.options` are defined in `resolv.h` and are as follows. Options are stored as a simple bit mask containing the bitwise or of the options enabled.

<code>RES_INIT</code>	True if the initial name server address and default domain name are initialized (that is, <code>res_init</code> has been called).
<code>RES_DEBUG</code>	Print debugging messages.
<code>RES_AAONLY</code>	Accept authoritative answers only. With this option, <code>res_send</code> should continue until it finds an authoritative answer or finds an error. Currently, this is not implemented.
<code>RES_USEVC</code>	Use TCP connections for queries instead of UDP datagrams.
<code>RES_STAYOPEN</code>	Used with <code>RES_USEVC</code> to keep the TCP connection open between queries. This is useful only in programs that regularly do many queries. UDP should be the normal mode used.
<code>RES_IGNTC</code>	Unused currently (ignore truncation errors—don't retry with TCP).
<code>RES_RECURSE</code>	Set the recursion-desired bit in queries. This is the default. (<code>res_send</code> does not do iterative queries and expects the name server to handle recursion.)

RES_DEFNAMES	If set, <code>res_search</code> will append the default domain name to single-component names (those that do not contain a dot). This option is enabled by default.
RES_DNSRCH	If this option is set, <code>res_search</code> will search for hostnames in the current domain and in parent domains; see <code>hostname(7)</code> . This is used by the standard host lookup routine <code>gethostbyname(3)</code> . This option is enabled by default.
RES_NOALIASES	This option turns off the user level aliasing feature controlled by the <code>HOSTALIASES</code> environment variable. Network daemons should set this option.

The `res_init` routine reads the configuration file (if any; see `resolver(5)`) to get the default domain name, search list and the Internet address of the local name server(s). If no server is configured, the host running the resolver is tried. The current domain name is defined by the `hostname` if not specified in the configuration file; it can be overridden by the environment variable `LOCALDOMAIN`. This environment variable may contain several blank-separated tokens if you wish to override the search list on a per-process basis. This is similar to the `search` command in the configuration file. Another environment variable (`RES_OPTIONS`) can be set to override certain internal resolver options that are otherwise set by changing fields in the `_res` structure or are inherited from the configuration file's options command. The syntax of the `RES_OPTIONS` environment variable is explained in `resolver(5)`. Initialization normally occurs on the first call to one of the other resolver routines.

The `res_query` function provides an interface to the server query mechanism. It constructs a query, sends it to the local server, awaits a response, and makes preliminary checks on the reply. The query requests information of the specified `type` and `class` for the specified fully-qualified domain name `dname`. The reply message is left in the `answer` buffer with length `ansl en` supplied by the caller.

The `res_search` routine makes a query and awaits a response like `res_query`, but in addition, it implements the default and search rules controlled by the `RES_DEFNAMES` and `RES_DNSRCH` options. It returns the first successful reply.

The remaining routines are lower-level routines used by `res_query`. The `res_mkquery` function constructs a standard query message and places it in `buf`. It returns the size of the query, or `-1` if the query is larger than `buflen`. The query `type` `op` is usually `QUERY`, but can be any of the query types defined in `<arpa/nameser.h>`. The domain name for the query is given by `dname`. `Newrr` is currently unused but is intended for making update messages.

The `res_send` routine sends a preformatted query and returns an answer. It will call `res_init` if `RES_INIT` is not set, send the query to the local name server, and handle time-outs and retries. The length of the reply message is returned, or `-1` if there were errors.

The `dn_comp` function compresses the domain name `exp_dn` and stores it in `comp_dn`. The size of the compressed name is returned or `-1` if there were errors. The size of the array pointed to by `comp_dn` is given by `length`. The compression uses an array of pointers `dnptrs` to previously-compressed names in the current message. The first pointer points to the beginning of the message and the list ends with `NULL`. The limit to the array is specified by `lastdnptr`. A side effect of `dn_comp` is to update the list of pointers for labels inserted into the message as the name is compressed. If `dnptr` is `NULL`, names are not compressed. If `lastdnptr` is `NULL`, the list of labels is not updated.

The `dn_expand` entry expands the compressed domain name `comp_dn` to a full domain name. The compressed name is contained in a query or reply message; `msg` is a pointer to the beginning of the message. The uncompressed name is placed in the buffer indicated by `exp_dn`, which is of size `length`. The size of compressed name is returned or `-1` if there was an error.

rewinddir

rewinddir—Resets directory stream

SYNOPSIS

```
#include <sys/types.h>
#include <dirent.h>
void rewinddir(DIR *dir);
```

DESCRIPTION

The `rewinddir()` function resets the position of the directory stream `dir` to the beginning of the directory.

RETURN VALUE

The `readdir()` function returns no value.

CONFORMS TO

rint

rint—Rounds to closest integer

SYNOPSIS

```
#include <math.h>
double rint(double x);
```

DESCRIPTION

The `rint()` function rounds `x` to an integer value according to the prevalent rounding mode. The default rounding mode is to round to the nearest integer.

RETURN VALUE

The `rint()` function returns the integer value as a floating-point number.

rquota

`rquota`—Implements quotas on remote machines

SYNOPSIS

```
/usr/include/rpcsvc/rquota.x
```

DESCRIPTION

The `rquota()` protocol inquires about quotas on remote machines. It is used in conjunction with NFS because NFS itself does not implement quotas.

PROGRAMMING

```
#include <rpcsvc/rquota.h>
```

The following XDR routines are available in `librpcsvc`: `xdr_getquota_arg`:

```
xdr_getquota_rslt
xdr_rquota
```

SEE ALSO

scandir, alphasort

`scandir`, `alphasort`—Scan a directory for matching entries

SYNOPSIS

```
#include <dirent.h>
int scandir(const char *dir, struct dirent ***namelist,
int (*select)(const struct dirent *),
int (*compar)(const struct dirent **, const struct dirent **));
int alphasort(const struct dirent **a, const struct dirent **b);
```

DESCRIPTION

The `scandir()` function scans the directory `dir`, calling `select()` on each directory entry. Entries for which `select()` returns non-zero are stored in strings allocated via `malloc()`, sorted using `qsort()` with the comparison function `compar()`, and collected in array `namelist` that is allocated via `malloc()`. If `select` is `NULL`, all entries are selected.

The `alphasort()` function can be used as the comparison function for the `scandir()` function to sort the directory entries into alphabetical order. Its parameters are the two directory entries, `a` and `b`, to compare.

RETURN VALUE

The `scandir()` function returns the number of directory entries selected or `-1` if an error occurs.

The `alphasort()` function returns an integer less than, equal to, or greater than zero if the first argument is considered to be respectively less than, equal to, or greater than the second.

ERRORS

ENOMEM

Insufficient memory to complete the operation

CONFORMS TO

BSD 4.3

EXAMPLE

```

/* print files in current directory in reverse order */
#include <dirent.h>
main(){
    struct dirent **namelist;
    int n;

    n = scandir(".", &namelist, 0, alphasort);
    if (n < 0)
        perror("scandir");
    else
        while(n--) printf("%s\n", namelist[n]->d_name);
}

scanf, fscanf, sscanf, vscanf, vsscanf, vfscanf

scanf, fscanf, sscanf, vscanf, vsscanf, vfscanf—Input format conversion

SYNOPSIS

```

#include <stdio.h>
int scanf( const char *format, ...);
int fscanf( FILE *stream, const char *format, ...);
int sscanf( const char *str, const char *format, ...);
#include <stdarg.h>
int vscanf( const char *format, va_list ap);
int vsscanf( const char *str, const char *format, va_list ap);
int vfscanf( FILE *stream, const char *format, va_list ap);

```

DESCRIPTION

The `scanf` family of functions scans input according to a format as described below. This format may contain conversion specifiers; the results from such conversions, if any, are stored through the pointer arguments. The `scanf` function reads input from the standard input stream `stdin`, `fscanf` reads input from the stream pointer `stream`, and `sscanf` reads its input from the character string pointed to by `str`.

The `vfscanf` function is analogous to `vfprintf(3)` and reads input from the stream pointer `stream` using a variable argument list of pointers (see `stdarg(3)`). The `vscanf` function scans a variable argument list from the standard input and the `vsscanf` function scans it from a string; these are analogous to the `vprintf` and `vsprintf` functions respectively.

Each successive pointer argument must correspond properly with each successive conversion specifier. All conversions are introduced by the `%` (percent sign) character. The format string may also contain other characters. Whitespace (such as blanks, tabs, or newlines) in the format string match any amount of whitespace, including none, in the input. Everything else matches only itself. Scanning stops when an input character does not match such a format character. Scanning also stops when an input conversion cannot be made.

CONVERSIONS

Following the % character introducing a conversion, there may be a number of flag characters, as follows:

- * Suppresses assignment. The conversion that follows occurs as usual, but no pointer is used; the result of the conversion is simply discarded.
- a Indicates that the conversion will be `s`, `malloc` will be applied to the needed memory space for the string, and the pointer to it will be assigned to the `char` pointer variable, which does not have to be initialized before. This flag does not exist in ANSI C.
- h Indicates that the conversion will be one of `dioux` or `n` and the next pointer is a pointer to a `short int` (rather than `int`).
- l Indicates either that the conversion will be one of `dioux` or `n` and the next pointer is a pointer to a `long int` (rather than `int`), or that the conversion will be one of `efg` and the next pointer is a pointer to `double` (rather than `float`). Specifying two `l` flags is equivalent to the `L` flag.
- L Indicates that the conversion will be either `efg` and the next pointer is a pointer to `long double` or the conversion will be `dioux` and the next pointer is a pointer to `long long`. (Note that `long long` is not an ANSI C type. Any program using this will not be portable to all architectures).
- q Equivalent to `L`. This flag does not exist in ANSI C.

In addition to these flags, there may be an optional maximum field width, expressed as a decimal integer, between the % and the conversion. If no width is given, a default of `infinity` is used (with one exception, below); otherwise, at most this many characters are scanned in processing the conversion. Before conversion begins, most conversions skip whitespace; this whitespace is not counted against the field width.

The following conversions are available:

- % Matches a literal %. That is, %% in the format string matches a single input % character. No conversion is done, and assignment does not occur.
- d Matches an optionally signed decimal integer; the next pointer must be a pointer to `int`.
- D Equivalent to `ld`; this exists only for backwards compatibility.
- i Matches an optionally signed integer; the next pointer must be a pointer to `int`. The integer is read in base 16 if it begins with `0x` or `0X`, in base 8 if it begins with `0`, and in base 10 otherwise. Only characters that correspond to the base are used.
- o Matches an unsigned octal integer; the next pointer must be a pointer to unsigned `int`.
- u Matches an unsigned decimal integer; the next pointer must be a pointer to unsigned `int`.
- x Matches an unsigned hexadecimal integer; the next pointer must be a pointer to unsigned `int`.
- X Equivalent to `x`.
- f Matches an optionally signed floating-point number; the next pointer must be a pointer to `float`.
- e Equivalent to `f`.
- g Equivalent to `f`.
- E Equivalent to `f`.
- s Matches a sequence of nonwhitespace characters; the next pointer must be a pointer to `char`, and the array must be large enough to accept all the sequence and the terminating NUL character. The input string stops at whitespace or at the maximum field width, whichever occurs first.
- c Matches a sequence of width count characters (default 1); the next pointer must be a pointer to `char`, and there must be enough room for all the characters (no terminating NUL is added). The usual skip of leading whitespace is suppressed. To skip whitespace first, use an explicit space in the format.
- [Matches a nonempty sequence of characters from the specified set of accepted characters; the next pointer must be a pointer to `char`, and there must be enough room for all the characters in the string, plus a terminating NUL character. The usual skip of leading whitespace is suppressed. The string is to be made up of characters in (or not in) a particular set; the set is defined by the characters between the open bracket [character and a close bracket] character. The set excludes those characters if the first

character after the open bracket is a circumflex (^). To include a close bracket in the set, make it the first character after the open bracket or the circumflex; any other position will end the set. The hyphen character (-) is also special; when placed between two other characters, it adds all intervening characters to the set. To include a hyphen, make it the last character before the final close bracket. For instance, [^]0-9-] means the set “everything except close bracket, zero through nine, and hyphen.” The string ends with the appearance of a character not in (or, with a circumflex, in) the set or when the field width runs out.

- p Matches a pointer value (as printed by %p in printf(3); the next pointer must be a pointer to void.
- n Nothing is expected; instead, the number of characters consumed thus far from the input is stored through the next pointer, which must be a pointer to int. This is not a conversion, although it can be suppressed with the * flag.

RETURN VALUES

These functions return the number of input items assigned, which can be fewer than provided for, or even zero, in the event of a matching failure. Zero indicates that, while there was input available, no conversions were assigned; typically, this is due to an invalid input character, such as an alphabetic character for a %d conversion. The value EOF is returned if an input failure occurs before any conversion such as an end-of-file occurs. If an error or end-of-file occurs after conversion has begun, the number of conversions which were successfully completed is returned.

SEE ALSO

strtoul(3), strtoul(3), strtod(3),getc(3),printf(3)

STANDARDS

The functions fscanf, scanf, and sscanf conform to ANSI C3.159-1989 (ANSI C).

The q flag is the BSD 4.4 notation for long long, while ll or the usage of L in integer conversions is the GNU notation.

The Linux version of these functions is based on the GNU libc library. Take a look at the info documentation of GNU libc (glibc-1.08) for a more concise description.

BUGS

All functions are fully ANSI C3.159-1989-conformant, but provide the additional flags q and a as well as an additional behavior of the L and l flags. The latter may be considered to be a bug, as it changes the behavior of flags defined in ANSI C3.159-1989.

Some combinations of flags defined by ANSI C are not making sense in ANSI C (for example, %Ld). While they may have a well-defined behavior on Linux, this need not to be so on other architectures. Therefore, it usually is better to use flags that are not defined by ANSI C at all, that is, use q instead of L in combination with dioux conversions or ll.

The usage of q is not the same as on BSD 4.4, as it may be used in float conversions equivalently to L.

Linux man page, 1 November 1995

seekdir

seekdir—Sets the position of the next readdir() call in the directory stream.

SYNOPSIS

```
#include <dirent.h>
void seekdir(DIR *dir, off_t offset);
```

DESCRIPTION

The seekdir() function sets the location in the directory stream from which the next readdir() call will start. seekdir() should be used with an offset returned by telldir().

RETURN VALUE

The `seekdir()` function returns no value.

CONFORMS TO

BSD 4.3

setbuf, setbuffer, setlinebuf, setvbuf

setbuf, setbuffer, setlinebuf, setvbuf—Stream buffering operations

SYNOPSIS

```
#include <stdio.h>

int setbuf( FILE *stream, char *buf);
int setbuffer( FILE *stream, char *buf, size_t size);
int setlinebuf( FILE *stream);
int setvbuf( FILE *stream, char *buf, int mode, size_t size);
```

DESCRIPTION

The three types of buffering available are unbuffered, block buffered, and line buffered. When an output stream is unbuffered, information appears on the destination file or terminal as soon as written; when it is block buffered, many characters are saved up and written as a block; when it is line buffered, characters are saved up until a newline is output or input is read from any stream attached to a terminal device (typically `stdin`). The function `fflush(3)` may be used to force the block out early. (See `fclose(3)`.) Normally all files are block buffered. When the first I/O operation occurs on a file, `malloc(3)` is called, and a buffer is obtained. If a stream refers to a terminal (as `stdout` normally does), it is line buffered. The standard error stream `stderr` is always unbuffered.

The `setvbuf` function may be used at any time on any open stream to change its buffer. The mode parameter must be one of the following three macros:

<code>_IONBF</code>	Unbuffered
<code>_IOLBF</code>	Line buffered
<code>_IOFBF</code>	Fully buffered

Except for unbuffered files, the `buf` argument should point to a buffer at least `size` bytes long; this buffer will be used instead of the current buffer. If the argument `buf` is `NULL`, only the mode is affected; a new buffer will be allocated on the next read or write operation. The `setvbuf` function may be used at any time, but can only change the mode of a stream when it is not “active”; that is, before any I/O, or immediately after a call to `fflush`.

The other three calls are, in effect, simply aliases for calls to `setvbuf`. The `setbuf` function is exactly equivalent to the call:

```
setvbuf(stream, buf, buf ? _IOFBF : _IONBF, BUFSIZ);
```

The `setbuffer` function is the same, except that the size of the buffer is up to the caller, rather than being determined by the default `BUFSIZ`. The `setlinebuf` function is exactly equivalent to the call:

```
setvbuf(stream, (char *)NULL, _IOLBF, 0);
```

SEE ALSO

fopen(3), fclose(3), fread(3), malloc(3), puts(3), printf(3)

STANDARDS

The `setbuf` and `setvbuf` functions conform to ANSI C3.159-1989 (ANSI C).

BUGS

The `setbuffer` and `setlinebuf` functions are not portable to versions of BSD before 4.2BSD, and may not be available under Linux. On 4.2BSD and 4.3BSD systems, `setbuf` always uses a suboptimal buffer size and should be avoided. You must make sure that both `buf` and the space it points to still exist by the time `stream` is closed, which also happens at program termination. For example, the following is illegal:

```
#include <stdio.h>
int main()
{
    char buf[BUFSIZ];
    setbuf(stdin, buf);
    printf("Hello, world!\n");
    return 0;
}
```

BSD man page, 29 November 1993

setenv

`setenv`—Changes or adds an environment variable

SYNOPSIS

```
#include <stdlib.h>
int setenv(const char *name, const char *value, int overwrite);
void unsetenv(const char *name);
```

DESCRIPTION

The `setenv()` function adds the variable `name` to the environment with the value `value`, if `name` does not already exist. If `name` does exist in the environment, then its value is changed to `value` if `overwrite` is non-zero; if `overwrite` is zero, then the value of `name` is not changed.

The `unsetenv()` function deletes the variable `name` from the environment.

RETURN VALUE

The `setenv()` function returns zero on success, or `-1` if there was insufficient space in the environment.

CONFORMS TO

BSD 4.3

setjmp

setjmp—Saves stack context for nonlocal goto

SYNOPSIS

```
#include <setjmp.h>
int setjmp(jmp_buf env );
```

DESCRIPTION

setjmp and longjmp(3) are useful for dealing with errors and interrupts encountered in a low-level subroutine of a program. setjmp() saves the stack context/environment in env for later use by longjmp(). The stack context will be invalidated if the function which called setjmp() returns.

RETURN VALUE

It returns the value 0 if returning directly and non-zero when returning from longjmp() using the saved context.

CONFORMS TO

POSIX

NOTES

POSIX does not specify if the signal context will be saved or not. If you want to save signal masks, use sigsetjmp(3). setjmp() makes programs hard to understand and maintain. If possible, an alternative should be used.

SEE ALSO

longjmp(3), sigsetjmp(2), siglongjmp(2)

setlocale

setlocale—Sets the current locale

SYNOPSIS

```
#include <locale.h>
char *setlocale(int category, const char * locale);
```

DESCRIPTION

The setlocale() function is used to set or query the program's current locale. If locale is C or POSIX, the current locale is set to the portable locale.

If locale is "", the locale is set to the default locale that is selected from the environment variable LANG.

On startup of the main program, the portable locale is selected as default.

The argument category determines which functions are influenced by the new locale:

LC_ALL	For all of the locale.
LC_COLLATE	For the functions strcoll() and strxfrm().
LC_CTYPE	For the character classification and conversion routines.
LC_MONETARY	For localeconv().
LC_NUMERIC	For the decimal character.
LC_TIME	For strftime(). NULL if the request can not be honored. This string may be allocated in static storage.

A program may be made portable to all locales by calling `setlocale(LC_ALL, "*****")` after program initialization, by using the values returned from a `localeconv()` call for locale-dependent information and by using `strcoll()` or `strxfrm()` to compare strings.

CONFORMS TO

ANSI C, POSIX.1

Linux supports the portable locales C and POSIX and also the European Latin-1 and Russian locales.

The `printf()` family of functions may or may not honor the current locale.

GNU, 18 April 1993

siginterrupt

`siginterrupt`—Allows signals to interrupt system calls

SYNOPSIS

```
#include <signal.h>
int siginterrupt(int sig, int flag);
```

DESCRIPTION

The `siginterrupt()` function changes the restart behavior when a system call is interrupted by the signal `sig`. If the `flag` argument is false (0), then systems calls will be restarted if interrupted by the specified signal `sig`. This is the default behavior in Linux. However, when a new signal handler is specified with the `signal(2)` function, the system call is interrupted by default.

If the `flag` argument is true (1) and no data has been transferred, then a system call interrupted by the signal `sig` will return -1 and the global variable `errno` will be set to `EINTR`.

If the `flag` argument is true (1) and data transfer has started, then the system call will be interrupted and will return the actual amount of data transferred.

RETURN VALUE

The `siginterrupt()` function returns 0 on success, or -1 if the signal number `sig` is invalid.

ERRORS

`EINVAL` The specified signal number is invalid.

CONFORMS TO

BSD 4.3

SEE ALSO

`signal(2)`

sigemptyset, sigfillset, sigaddset, sigdelset, sigismember

`sigemptyset, sigfillset, sigaddset, sigdelset, sigismember`—POSIX signal set operations

SYNOPSIS

```
#include <signal.h>
int sigemptyset(sigset_t *set);
int sigfillset(sigset_t *set);
int sigaddset(sigset_t *set, int signum);
int sigdelset(sigset_t *set, int signum);
int sigismember(const sigset_t *set, int signum);
```

DESCRIPTION

The `sigsetops(3)` functions allow the manipulation of POSIX signal sets.

`sigemptyset` initializes the signal set given by `set` to empty, with all signals excluded from the set.

`sigfillset` initializes `set` to full, including all signals.

`sigaddset` and `sigdelset` add and delete, respectively, signal `signum` from `set`.

`sigismember` tests whether `signum` is a member of `set`.

RETURN VALUES

`sigemptyset`, `sigfullset`, `sigaddset`, and `sigdelset` return 0 on success and -1 on error.

`sigismember` returns 1 if `signum` is a member of `set`, 0 if `signum` is not a member, and -1 on error.

ERRORS

`EINVAL` `sig` is not a valid signal.

CONFORMS TO

POSIX

sin

`sin`—Sine function

SYNOPSIS

```
#include <math.h>
double sin(double x);
```

DESCRIPTION

The `sin()` function returns the sine of `x`, where `x` is given in radians.

RETURN VALUE

The `sin()` function returns a value between -1 and 1.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

sleep

`sleep`—Sleeps for the specified number of seconds

SYNOPSIS

```
#include <unistd.h>
unsigned int sleep(unsigned int seconds);
```

DESCRIPTION

`sleep()` makes the current process sleep until `seconds` seconds have elapsed or a signal arrives that is not ignored.

RETURN VALUE

The return value is zero if the requested time has elapsed, or the number of seconds left to sleep.

CONFORMS TO

POSIX.1

BUGS

`sleep()` may be implemented using `SIGALRM`; mixing calls to `alarm()` and `sleep()` is a bad idea.

Using `longjmp()` from a signal handler or modifying the handling of `SIGALRM` while sleeping will cause undefined results.

SEE ALSO

`signal(2)`, `alarm(2)`

GNU, 7 April 1993

snprintf, vsnprintf

snprintf, vsnprintf—Formatted output conversion

SYNOPSIS

```
#include <stdio.h>

int snprintf ( char *str, size_t n,
              const char *format, ... );

#include <stdarg.h>

int vsnprintf ( char *str, size_t n,
              const char *format, va_list ap );
```

DESCRIPTION

`snprintf` writes output to the string `str`, under control of the `format` string that specifies how subsequent arguments are converted for output. It is similar to `sprintf(3)`, except that `n` specifies the maximum number of characters to produce. The trailing null character is counted towards this limit, so you should allocate at least `n` characters for the string `str`.

`vsnprintf` is the equivalent of `snprintf` with the variable argument list specified directly as for `vprintf`.

RETURN VALUE

The return value is the number of characters stored, not including the terminating null. If this value equals `n`, then there was not enough space in `str` for all the output. You should try again with a bigger output string.

EXAMPLE

Here is a sample program that dynamically enlarges its output buffer:

```
/* Construct a message describing the value of a
   variable whose name is NAME and whose value is
   VALUE. */
char *
make_message (char *name, char *value)
{
    /* Guess we need no more than 100 chars of space. */
    int size = 100;
    char *buffer = (char *) xmalloc (size);
    while (1)
    {
        /* Try to print in the allocated space. */
        int nchars = snprintf (buffer, size,
                               "value of %s is %s", name, value);
        /* If that worked, return the string. */
        if (nchars < size)
            return buffer;
        /* Else try again with twice as much space. */
        size *= 2;
        buffer = (char *) xrealloc (size, buffer);
    }
}
```

CONFORMS TO

stdarg

stdarg—Variable argument lists

SYNOPSIS

```
#include <stdarg.h>
void va_start( va_list ap, last);
type va_arg( va_list ap, type);
void va_end( va_list ap);
```

DESCRIPTION

A function may be called with a varying number of arguments of varying types. The include file `stdarg.h` declares a type `va_list` and defines three macros for stepping through a list of arguments whose number and types are not known to the called function.

The called function must declare an object of type `va_list` that is used by the macros `va_start`, `va_arg`, and `va_end`.

The `va_start` macro initializes `ap` for subsequent use by `va_arg` and `va_end`, and must be called first.

The parameter `last` is the name of the last parameter before the variable argument list; that is, the last parameter of which the calling function knows the type.

Because the address of this parameter is used in the `va_start` macro, it should not be declared as a register variable, a function, or an array type.

The `va_start` macro returns no value.

The `va_arg` macro expands to an expression that has the type and value of the next argument in the call. The parameter `ap` is the `va_list` `ap` initialized by `va_start`. Each call to `va_arg` modifies `ap` so that the next call returns the next argument. The parameter type is a type name specified so that the type of a pointer to an object that has the specified type can be obtained simply by adding a `*` to `type`.

If there is no next argument, or if `type` is not compatible with the type of the actual next argument (as promoted according to the default argument promotions), random errors will occur.

The first use of the `va_arg` macro after that of the `va_start` macro returns the argument after last. Successive invocations return the values of the remaining arguments.

The `va_end` macro handles a normal return from the function whose variable argument list was initialized by `va_start`.

The `va_end` macro returns no value.

EXAMPLE

The function `foo` takes a string of format characters and prints out the argument associated with each format character based on the type.

```
void foo(char *fmt, ...)
{
    va_list ap;
    int d;
    char c, *p, *s;

    va_start(ap, fmt);
    while (*fmt)
        switch(*fmt++) {
            case 's':          /* string */
                s = va_arg(ap, char *);
                printf("string %s\n", s);
                break;
            case 'd':          /* int */
                d = va_arg(ap, int);
                printf("int %d\n", d);
                break;
            case 'c':          /* char */
                c = va_arg(ap, char);
                printf("char %c\n", c);
                break;
        }
    va_end(ap);
}
```

STANDARDS

The `va_start`, `va_arg`, and `va_end` macros conform to ANSI C3.159-1989 (ANSI C).

COMPATIBILITY

These macros are not compatible with the historic macros they replace. A backwards-compatible version can be found in the include file `varargs.h`.

BUGS

Unlike the `varargs` macros, the `stdarg` macros do not permit programmers to code a function with no fixed arguments. This problem generates work mainly when converting `varargs` code to `stdarg` code, but it also creates difficulties for `variadic` functions that wish to pass all of their arguments on to a function that takes a `va_list` argument, such as `vfprintf(3)`.

stdio

stdio—Standard input/output library functions

SYNOPSIS

```
#include <stdio.h>
FILE *stdin;
FILE *stdout;
FILE *stderr;
```

DESCRIPTION

The standard I/O library provides a simple and efficient buffered stream I/O interface. Input and output is mapped into logical data streams and the physical I/O characteristics are concealed. The functions and macros are listed in this section; more information is available from the individual man pages.

A stream is associated with an external file (which may be a physical device) by opening a file, which may involve creating a new file. Creating an existing file causes its former contents to be discarded. If a file can support positioning requests (such as a disk file, as opposed to a terminal), then a file position indicator associated with the stream is positioned at the start of the file (byte zero), unless the file is opened with append mode. If append mode is used, the position indicator will be placed the end-of-file. The position indicator is maintained by subsequent reads, writes, and positioning requests. All input occurs as if the characters were read by successive calls to the `fgetc(3)` function; all output takes place as if all characters were read by successive calls to the `fputc(3)` function.

A file is disassociated from a stream by closing the file. Output streams are flushed (any unwritten buffer contents are transferred to the host environment) before the stream is disassociated from the file. The value of a pointer to a `FILE` object is indeterminate after a file is closed (garbage).

A file may be subsequently reopened, by the same or another program execution, and its contents reclaimed or modified (if it can be repositioned at the start). If the main function returns to its original caller, or the `exit(3)` function is called, all open files are closed (hence all output streams are flushed) before program termination. Other methods of program termination, such as `abort(3)` do not bother about closing files properly.

At program startup, three text streams are predefined and need not be opened explicitly: standard input (for reading conventional input), standard output (for writing conventional input), and standard error (for writing diagnostic output). These streams are abbreviated `stdin`, `stdout`, and `stderr`. When opened, the standard error stream is not fully buffered; the standard input and output streams are fully buffered if and only if the streams do not refer to an interactive device.

Output streams that refer to terminal devices are always line buffered by default; pending output to such streams is written automatically whenever an input stream that refers to a terminal device is read. In cases where a large amount of computation is done after printing part of a line on an output terminal, it is necessary to `fflush(3)` the standard output before going off and computing so that the output will appear.

The `stdio` library is a part of the library `libc` and routines are automatically loaded as needed by the compilers `cc(1)` and `pc(1)`. The `SYNOPSIS` sections of the following manual pages indicate which include files are to be used, what the compiler declaration for the function looks like, and which external variables are of interest.

The following are defined as macros; these names may not be reused without first removing their current definitions with `#undef`: `BUFSIZ`, `EOF`, `FILENAME_MAX`, `FOPEN_MAX`, `L_cuserid`, `L_ctermid`, `L_tmpnam`, `NULL`, `SEEK_END`, `SEEK_SET`, `SEEK_CUR`, `TMP_MAX`, `clearerr`, `feof`, `ferror`, `fileno`, `fopen`, `fwopen`, `getc`, `getchar`, `putc`, `putchar`, `stderr`, `stdin`, `stdout`. Function versions of the macro functions `feof`, `ferror`, `clearerr`, `fileno`, `getc`, `getchar`, `putc`, and `putchar` exist and will be used if the macros definitions are explicitly removed.

SEE ALSO

`open(2)`, `close(2)`, `read(2)`, `write(2)`

BUGS

The standard buffered functions do not interact well with certain other library and system functions, especially `vfork` and `abort`. This may not be the case under Linux.

STANDARDS

The `stdio` library conforms to ANSI C3.159-1989 (ANSI C).

LIST OF FUNCTIONS

<i>Function</i>	<i>Description</i>
<code>clearerr</code>	Check and reset stream status
<code>fclose</code>	Close a stream
<code>fdopen</code>	Stream open functions
<code>feof</code>	Check and reset stream status
<code>ferror</code>	Check and reset stream status
<code>fflush</code>	Flush a stream
<code>fgetc</code>	Get next character or word from input stream
<code>fgetline</code>	Get a line from a stream
<code>fgetpos</code>	Reposition a stream
<code>fgets</code>	Get a line from a stream
<code>fileno</code>	Check and reset stream status
<code>fopen</code>	Stream open functions
<code>fprintf</code>	Formatted output conversion
<code>fpurge</code>	Flush a stream
<code>fputc</code>	Output a character or word to a stream
<code>fputs</code>	Output a line to a stream
<code>fread</code>	Binary stream input/output
<code>freopen</code>	Stream open functions
<code>fropen</code>	Open a stream
<code>fscanf</code>	Input format conversion
<code>fseek</code>	Reposition a stream
<code>fsetpos</code>	Reposition a stream
<code>ftell</code>	Reposition a stream
<code>fwrite</code>	Binary stream input/output
<code>getc</code>	Get next character or word from input stream
<code>getchar</code>	Get next character or word from input stream
<code>gets</code>	Get a line from a stream
<code>getw</code>	Get next character or word from input stream
<code>mktemp</code>	Make temporary filename (unique)
<code>perror</code>	System error messages
<code>printf</code>	Formatted output conversion
<code>putc</code>	Output a character or word to a stream
<code>putchar</code>	Output a character or word to a stream
<code>puts</code>	Output a line to a stream
<code>putw</code>	Output a character or word to a stream

remove	Remove directory entry
rewind	Reposition a stream
scanf	Input format conversion
setbuf	Stream buffering operations
setbuffer	Stream buffering operations
setlinebuf	Stream buffering operations

stpcpy

stpcpy—Copies a string returning a pointer to its end

SYNOPSIS

```
#include <string.h>
char *stpcpy(char *dest, const char *src);
```

DESCRIPTION

The `stpcpy()` function copies the string pointed to by `src` (including the terminating `\0` character) to the array pointed to by `dest`. The strings may not overlap, and the destination string `dest` must be large enough to receive the copy.

RETURN VALUE

`stpcpy()` returns a pointer to the end of the string `dest` (that is, the address of the terminating null character) rather than the beginning.

EXAMPLE

For example, this program uses `stpcpy` to concatenate `foo` and `bar` to produce `foobar`, which it then prints:

```
#include <string.h>

int
main (void)
{
```

```

char *to = buffer;
to = stpcpy (to, "foo");
to = stpcpy (to, "bar");
printf ("%s\n", buffer);
}

```

CONFORMS TO

This function is not part of the ANSI or POSIX standards, and is not customary on UNIX systems, but is not a GNU invention either. Perhaps it comes from MS-DOS.

GNU, 3 September 1995

strcasecmp, strncasecmp

`strcasecmp`, `strncasecmp`—Compare two strings, ignoring case

SYNOPSIS

```

#include <string.h>
int strcasecmp(const char *s1, const char *s2);
int strncasecmp(const char *s1, const char *s2, size_t n);

```

DESCRIPTION

The `strcasecmp()` function compares the two strings `s1` and `s2`, ignoring the case of the characters. It returns an integer less than, equal to, or greater than zero if `s1` is found, respectively, to be less than, to match, or be greater than `s2`.

The `strncasecmp()` function is similar, except it only compares the first `n` characters of `s1`.

RETURN VALUE

The `strcasecmp()` and `strncasecmp()` functions return an integer less than, equal to, or greater than zero if `s1` (or the first `n` bytes thereof) is found, respectively, to be less than, to match, or be greater than `s2`.

CONFORMS TO

BSD 4.3

SEE ALSO

11 April 1993

strcat, strncat

`strcat`, `strncat`—Concatenate two strings

SYNOPSIS

```

#include <string.h>
char *strcat(char *dest, const char *src);
char *strncat(char *dest, const char *src, size_t n);

```

DESCRIPTION

The `strcat()` function appends the `src` string to the `dest` string, overwriting the `\0` character at the end of `dest`, and then adds a terminating `\0` character. The strings may not overlap, and the `dest` string must have enough space for the result.

The `strncat()` function is similar, except that only the first `n` characters of `src` are appended to `dest`.

RETURN VALUE

The `strcat()` and `strncat()` functions return a pointer to the resulting string `dest`.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

`bcopy(3)`, `memccpy(3)`, `memcpy(3)`, `strcpy(3)`, `strncpy(3)`

strchr, strrchr

`strchr`, `strrchr`—Locate character in string

SYNOPSIS

```
#include <string.h>
char *strchr(const char *s, int c);
char *strrchr(const char *s, int c);
```

DESCRIPTION

The `strchr()` function returns a pointer to the first occurrence of the character `c` in the string `s`.

The `strrchr()` function returns a pointer to the last occurrence of the character `c` in the string `s`.

RETURN VALUE

The `strchr()` and `strrchr()` functions return a pointer to the matched character or `NULL` if the character is not found.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

`index(3)`, `memchr(3)`, `rindex(3)`, `strpbrk(3)`, `strsep(3)`, `strspn(3)`, `strstr(3)`, `strtok(3)`

12 April 1993

strcmp, strncmp

`strcmp`, `strncmp`—Compare two strings

SYNOPSIS

```
#include <string.h>
int strcmp(const char *s1, const char *s2);
int strncmp(const char *s1, const char *s2, size_t n);
```

DESCRIPTION

The `strcmp()` function compares the two strings `s1` and `s2`. It returns an integer less than, equal to, or greater than zero if `s1` is found, respectively, to be less than, to match, or be greater than `s2`.

The `strncmp()` function is similar, except it only compares the first `n` characters of `s1`.

RETURN VALUE

The `strcmp()` and `strncmp()` functions return an integer less than, equal to, or greater than zero if `s1` (or the first `n` bytes thereof) is found, respectively, to be less than, to match, or be greater than `s2`.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

`bcmp(3)`, `memcmp(3)`, `strcasemp(3)`, `strncasemp(3)`, `strcoll(3)`

11 April 1993

strcoll

`strcoll`—Compares two strings using the current locale

SYNOPSIS

```
#include <string.h>
int strcoll(const char *s1, const char *s2);
```

DESCRIPTION

The `strcoll()` function compares the two strings `s1` and `s2`. It returns an integer less than, equal to, or greater than zero if `s1` is found, respectively, to be less than, to match, or be greater than `s2`. The comparison is based on strings interpreted as appropriate for the program's current locale for category `LC_COLLATE`. (See `setlocale(3)`).

RETURN VALUE

The `strcoll()` function returns an integer less than, equal to, or greater than zero if `s1` is found, respectively, to be less than, to match, or be greater than `s2`, when both are interpreted as appropriate for the current locale.

CONFORMS TO

SVID 3, BSD 4.3, ISO 9899

NOTES

The Linux C Library currently hasn't implemented the complete POSIX-collating.

In the POSIX or C locales, `strcoll()` is equivalent to `strcmp()`.

strcpy, strncpy

`strcpy`, `strncpy`—Copy a string

SYNOPSIS

```
#include <string.h>
char *strcpy(char *dest, const char *src);
char *strncpy(char *dest, const char *src, size_t n);
```

DESCRIPTION

The `strcpy()` function copies the string pointed to by `src` (including the terminating `\0` character) to the array pointed to by `dest`. The strings may not overlap, and the destination string `dest` must be large enough to receive the copy.

The `strncpy()` function is similar, except that not more than `n` bytes of `src` are copied. Thus, if there is no null byte among the first `n` bytes of `src`, the result will not be null-terminated.

In the case where the length of `src` is less than that of `n`, the remainder of `dest` will be padded with nulls.

RETURN VALUE

The `strcpy()` and `strncpy()` functions return a pointer to the destination string `dest`.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

`bcopy(3)`, `memcpy(3)`, `memmove(3)`

GNU, 11 April 1993

strdup

`strdup`—Duplicates a string

SYNOPSIS

```
#include <string.h>
char *strdup(const char *s);
```

DESCRIPTION

The `strdup()` function returns a pointer to a new string that is a duplicate of the string `s`. Memory for the new string is obtained with `malloc(3)`, and can be freed with `free(3)`.

RETURN VALUE

The `strdup()` function returns a pointer to the duplicated string, or `NULL` if insufficient memory was available.

ERRORS

`ENOMEM`

Insufficient memory available to allocate duplicate string

CONFORMS TO

SVID 3, BSD 4.3

SEE ALSO

`calloc(3)`, `malloc(3)`, `realloc(3)`, `free(3)`

GNU, 12 April 1993

strerror

`strerror`—Returns string describing error code

SYNOPSIS

```
#include <string.h>
char *strerror(int errnum);
```

DESCRIPTION

The `strerror()` function returns a string describing the error code passed in the argument `errnum`. The string can only be used until the next call to `strerror()`.

RETURN VALUE

The `strerror()` function returns the appropriate description string, or an unknown error message if the error code is unknown.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

`errno(3)`, `perror(3)`, `strsignal(3)`

GNU, 13 April 1993

strfry

`strfry`—Randomizes a string

SYNOPSIS

```
#include <string.h>
char *strfry(char *string);
```

DESCRIPTION

The `strfry()` function randomizes the contents of `string` by using `rand(3)` to randomly swap characters in the string. The result is an anagram of `string`.

RETURN VALUE

The `strfry()` function returns a pointer to the randomized string.

CONFORMS TO

The `strfry()` function is unique to the Linux C Library and GNU C Library.

SEE ALSO

`memfrob(3)`

GNU, 12 April 1993

strftime

`strftime`—Formats date and time

SYNOPSIS

```
#include <time.h>
size_t strftime(char *s, size_t max, const char *format,
const struct tm *tm);
```

DESCRIPTION

The `strftime()` function formats the broken-down time `tm` according to the format specification `format` and places the result in the character array `s` of size `max`.

Ordinary characters placed in the format string are copied to `s` without conversion. Conversion specifiers are introduced by a `%` character, and are replaced in `s` as follows:

<code>%a</code>	The abbreviated weekday name according to the current locale
<code>%A</code>	The full weekday name according to the current locale
<code>%b</code>	The abbreviated month name according to the current locale
<code>%B</code>	The full month name according to the current locale
<code>%c</code>	The preferred date and time representation for the current locale
<code>%d</code>	The day of the month as a decimal number (range 01 to 31)
<code>%H</code>	The hour as a decimal number using a 24-hour clock (range 00 to 23)
<code>%I</code>	The hour as a decimal number using a 12-hour clock (range 01 to 12)
<code>%j</code>	The day of the year as a decimal number (range 001 to 366)
<code>%m</code>	The month as a decimal number (range 01 to 12)
<code>%M</code>	The minute as a decimal number
<code>%p</code>	Either a.m. or p.m. according to the given time value, or the corresponding strings for the current locale
<code>%S</code>	The second as a decimal number
<code>%U</code>	The week number of the current year as a decimal number, starting with the first Sunday as the first day of the first week
<code>%W</code>	The week number of the current year as a decimal number, starting with the first Monday as the first day of the first week
<code>%w</code>	The day of the week as a decimal, Sunday being 0
<code>%x</code>	The preferred date representation for the current locale without the time
<code>%X</code>	The preferred time representation for the current locale without the date
<code>%y</code>	The year as a decimal number without a century (range 00 to 99)
<code>%Y</code>	The year as a decimal number including the century
<code>%Z</code>	The time zone or name or abbreviation
<code>%%</code>	A literal <code>%</code> character

The broken-down time structure `tm` is defined in `<time.h>` as follows:

```
struct tm
{
int tm sec; /* seconds */
int tm min; /* minutes */
int tm hour; /* hours */
int tm mday; /* day of the month */
int tm mon; /* month */
int tm year; /* year */
int tm wday; /* day of the week */
int tm yday; /* day in the year */
int tm isdst; /* daylight saving time */
};
```

The members of the `tm` structure are

<code>tm_sec</code>	The number of seconds after the minute, normally in the range 0 to 59, but can be up to 61 to allow for leap seconds.
<code>tm_min</code>	The number of minutes after the hour, in the range 0 to 59.
<code>tm_hour</code>	The number of hours past midnight, in the range 0 to 23.
<code>tm_mday</code>	The day of the month, in the range 1 to 31.
<code>tm_mon</code>	The number of months since January, in the range 0 to 11.
<code>tm_year</code>	The number of years since 1900.
<code>tm_wday</code>	The number of days since Sunday, in the range 0 to 6.
<code>tm_yday</code>	The number of days since January 1, in the range 0 to 365.
<code>tm_isdst</code>	A flag that indicates whether daylight saving time is in effect at the time described. The value is positive if daylight saving time is in effect, zero if it is not, and negative if the information is not available.

RETURN VALUE

The `strptime()` function returns the number of characters placed in the array `s`, not including the terminating `NULL` character. If the value equals `max`, it means that the array was too small.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

strlen

strlen—Calculates the length of a string

SYNOPSIS

```

#include <string.h>
size_t strlen(const char *s);

```

DESCRIPTION

The strlen() function calculates the length of the string s, not including the terminating \0 character.

RETURN VALUE

The strlen() function returns the number of characters in s.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

SEE ALSO

strptime

`strptime`—Converts a string representation of time to a time `tm` structure

SYNOPSIS

```
#include <time.h>
char *strptime(char *buf, const char *format, const struct tm *tm);
```

DESCRIPTION

`strptime()` is the complementary function to `strftime()` and converts the character string pointed to by `buf` to a time value, which is stored in the `tm` structure pointed to by `tm`, using the format specified by `format`. `format` is a character string that consists of field descriptors and text characters, reminiscent of `scanf(3)`. Each field descriptor consists of a `%` character followed by another character that specifies the replacement for the field descriptor. All other characters are copied from `format` into the result. The following field descriptors are supported:

<code>%%</code>	Same as <code>%</code> .
<code>%a, %A</code>	Day of week, using locale's weekday names; either the abbreviated or full name may be specified.
<code>%b, %B, %h</code>	Month, using locale's month names; either the abbreviated or full name may be specified.
<code>%c</code>	Date and time as <code>%x, %X</code> .
<code>%C</code>	Date and time, in locale's long-format date and time representation.
<code>%d, %e</code>	Day of month (1–31; leading zeroes are permitted but not required).
<code>%D</code>	Date as <code>%m/%d/%y</code> .
<code>%H, %k</code>	Hour (0–23; leading zeroes are permitted but not required).
<code>%I, %l</code>	Hour (0–12; leading zeroes are permitted but not required).
<code>%j</code>	Day number of year (001–366).
<code>%m</code>	Month number (1–12; leading zeroes are permitted but not required).
<code>%M</code>	Minute (0–59; leading zeroes are permitted but not required).
<code>%p</code>	Locale's equivalent of a.m. or p.m.
<code>%r</code>	Time as <code>%I:%M:%S %p</code> .

%R	Time as %H:%M.
%S	Seconds (0–61; leading zeroes are permitted but not required; extra second allowed for leap years).
%T	Time as %H:%M:%S.
%w	Weekday number (0–6) with Sunday as the first day of the week.
%x	Date, using locale’s date format.
%X	Time, using locale’s time format.
%y	Year within century (0–99; leading zeroes are permitted but not required. Unfortunately, this makes the assumption that we are stuck in the 20th century, as 1900 is automatically added onto this number for the <code>tm</code> year field.)
%Y	Year, including century (for example, 1988).

Case is ignored when matching items such as month or weekday names.

The broken-down time structure `tm` is defined in `<time.h>` as follows:

```
struct tm
{
    int tm_sec; /* seconds */
    int tm_min; /* minutes */
    int tm_hour; /* hours */
    int tm_mday; /* day of the month */
    int tm_mon; /* month */
    int tm_year; /* year */
    int tm_wday; /* day of the week */
    int tm_yday; /* day in the year */
    int tm_isdst; /* daylight saving time */
};
```

RETURN VALUE

The `strptime()` function returns a pointer to the character following the last character in the string pointed to by `buf`.

SEE ALSO

`strftime(3)`, `time(2)`, `setlocale(3)`, `scanf(3)`

BUGS

The return values point to static data, whose contents are overwritten by each call.

NOTES

This function is only available in libraries newer than version 4.6.5.

The function supports only those locales specified in `locale(7)`.

GNU, 26 September 1994

strsep

`strsep`—Extracts token from string

SYNOPSIS

```
#include <string.h>
char *strsep(char **stringp, const char *delim);
```

DESCRIPTION

The `strsep()` function returns the next token from the string `stri n g p` which is delimited by `del i m`. The token is terminated with a `\0` character and `stri n g p` is updated to point past the token.

RETURN VALUE

The `strsep()` function returns a pointer to the token, or `NULL` if `delim` is not found in `stri n g p`.

CONFORMS TO

BSD 4.3

SEE ALSO

strsignal

`strsignal`—Returns string describing signal

SYNOPSIS

```
#include <string.h>
char *strsignal(int sig);
extern const char * const sys_siglist[]
```

DESCRIPTION

The `strsignal()` function returns a string describing the signal number passed in the argument `sig`. The string can only be used until the next call to `strsignal()`.

The array `sys_siglist` holds the signal description strings indexed by signal number.

RETURN VALUE

The `strsignal()` function returns the appropriate description string, or an unknown signal message if the signal number is invalid.

SEE ALSO

`psignal(3)`, `strerror(3)`

GNU, 13 April 1993

strspn, strcspn

`strspn, strcspn`—Search a string for a set of characters

SYNOPSIS

```
#include <string.h>
size_t strspn(const char *s, const char *accept);
size_t strcspn(const char *s, const char *reject);
```

DESCRIPTION

The `strspn()` function calculates the length of the initial segment of `s`, which consists entirely of characters in `accept`.

The `strcspn()` function calculates the length of the initial segment of `s`, which consists entirely of characters not in `reject`.

RETURN VALUE

The `strspn()` function returns the number of characters in the initial segment of `s`, which consist only of characters from `accept`.

The `strcspn()` function returns the number of characters in the initial segment of `s`, which are not in the string `reject`.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

strstr

`strstr`—Locates a substring

SYNOPSIS

```
#include <string.h>
char *strstr(const char *haystack, const char *needle);
```

DESCRIPTION

The `strstr()` function finds the first occurrence of the substring `needle` in the string `haystack`. The terminating `\0` characters are not compared.

RETURN VALUE

The `strstr()` function returns a pointer to the beginning of the substring, or `NULL` if the substring is not found.

GNU, 12 April 1993

strtod

`strtod`—Converts ASCII string to double

SYNOPSIS

```
#include <stdlib.h>
double strtod(const char *nptr, char **endptr);
```

DESCRIPTION

The `strtod()` function converts the initial portion of the string pointed to by `nptr` to double representation.

The expected form of the string is optional leading whitespace as checked by `isspace(3)`, an optional plus (+) or minus sign (-) followed by a sequence of digits optionally containing a decimal point character, optionally followed by an exponent. An exponent consists of an `E` or `e`, followed by an optional plus or minus sign, followed by a nonempty sequence of digits. If the locale is not `C` or `POSIX`, different formats may be used.

RETURN VALUES

The `strtod` function returns the converted value, if any.

If `endptr` is not `NULL`, a pointer to the character after the last character used in the conversion is stored in the location referenced by `endptr`.

If no conversion is performed, zero is returned and the value of `nptr` is stored in the location referenced by `endptr`.

If the correct value would cause overflow, plus or minus `HUGE_VAL` is returned (according to the sign of the value), and `ERANGE` is stored in `errno`. If the correct value would cause underflow, zero is returned and `ERANGE` is stored in `errno`.

ERRORS

`ERANGE` Overflow or underflow occurred.

CONFORMS TO

ANSI C

BSD man page, 4 March 1996

strtok

`strtok`—Extracts token from string

SYNOPSIS

```
#include <string.h>
char *strtok(char *s, const char *delim);
```

DESCRIPTION

A token is a nonempty string of characters not occurring in the string `delim`, followed by `\0` or by a character occurring in `delim`.

The `strtok()` function can be used to parse the string `s` into tokens. The first call to `strtok()` should have `s` as its first argument. Subsequent calls should have the first argument set to `NULL`. Each call returns a pointer to the next token, or `NULL` when no more tokens are found.

If a token ends with a delimiter, this delimiting character is overwritten with a `\0` and a pointer to the next character is saved for the next call to `strtok`. The delimiter string `delim` may be different for each call.

BUGS

This function modifies its first argument. The identity of the delimiting character is lost.

RETURN VALUE

The `strtok()` function returns a pointer to the next token, or `NULL` if there are no more tokens.

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

strtol

strtol—Converts a string to a long integer

SYNOPSIS

```
#include <stdlib.h>
long int strtol(const char *nptr, char **endptr, int base);
```

DESCRIPTION

The `strtol()` function converts the string in `nptr` to a long integer value according to the given base, which must be between 2 and 36 inclusive, or be the special value 0.

The string must begin with an arbitrary amount of whitespace (as determined by `isspace(3)`) followed by a single optional `+` or `-` sign. If base is zero or 16, the string may then include a `0x` prefix, and the number will be read in base 16; otherwise, a zero base is taken as 10 (decimal) unless the next character is 0, in which case it is taken as 8 (octal).

The remainder of the string is converted to a long `int` value in the obvious manner, stopping at the first character that is not a valid digit in the given base. (In bases above 10, the letter `A` in either upper- or lowercase represents 10, `B` represents 11, and so forth, with `z` representing 35.)

If `endptr` is not `NULL`, `strtol()` stores the address of the first invalid character in `*endptr`. If there were no digits at all, `strtol()` stores the original value of `nptr` in `*endptr`. (Thus, if `*nptr` is not `\0` but `**endptr` is `\0` on return, the entire string is valid.)

RETURN VALUE

The `strtol()` function returns the result of the conversion, unless the value would underflow or overflow. If an underflow occurs, `strtol()` returns `LONG_MIN`. If an overflow occurs, `strtol()` returns `LONG_MAX`. In both cases, `errno` is set to `ERANGE`.

ERRORS

`ERANGE` The given string was out of range; the value converted has been clamped.

CONFORMS TO

SVID 3, BSD 4.3, ISO 9899

BUGS

Ignores the current locale.

GNU, 10 June 1995

strtoul

strtoul—Converts a string to an unsigned long integer.

SYNOPSIS

```
#include <stdlib.h>
unsigned long int strtoul(const char *nptr, char **endptr,
int base);
```

DESCRIPTION

The `strtoul()` function converts the string in `nptr` to an unsigned long integer value according to the given base, which must be between 2 and 36 inclusive, or be the special value 0.

The string must begin with an arbitrary amount of whitespace (as determined by `isspace(3)`) followed by a single optional `+` or `-` sign. If base is zero or 16, the string may then include a `0x` prefix, and the number will be read in base 16; otherwise, a zero base is taken as 10 (decimal) unless the next character is 0, in which case it is taken as 8 (octal).

The remainder of the string is converted to an unsigned long `int` value in the obvious manner, stopping at the first character that is not a valid digit in the given base. (In bases above 10, the letter `A` in either upper- or lowercase represents 10, `B` represents 11, and so forth, with `Z` representing 35.)

If `endptr` is not `NULL`, `strtoul()` stores the address of the first invalid character in `*endptr`. If there were no digits at all, `strtoul()` stores the original value of `nptr` in `*endptr`. (Thus, if `*nptr` is not `\0` but `**endptr` is `\0` on return, the entire string is invalid.)

RETURN VALUE

The `strtoul()` function returns either the result of the conversion or, if there was a leading minus sign, the negation of the result of the conversion, unless the original (non-negated) value would overflow; in the latter case, `strtoul()` returns `ULONG_MAX` and sets the global variable `errno` to `ERANGE`.

ERRORS

`ERANGE` The given string was out of range; the value converted has been clamped.

CONFORMS TO

SVID 3, BSD 4.3, ISO 9899

BUGS

`strtoul` ignores the current locale.

GNU, 29 March 1993

strxfrm

`strxfrm`—String transformation

SYNOPSIS

```
#include <string.h>

size_t strxfrm(char *dest, const char *src, size_t n);
```

DESCRIPTION

The `strxfrm()` function transforms the `src` string into a form such that the result of `strcmp()` on two strings that have been transformed with `strxfrm()` is the same as the result of `strcmp()` on the two strings before their transformation. The first `n` characters of the transformed string are placed in `dest`. The transformation is based on the program's current locale for category `LC_COLLATE`. (See `setlocale(3)`).

RETURN VALUE

The `strxfrm()` function returns the number of bytes required to store the transformed string in `dest` excluding the terminating `\0` character. If the value returned is `n` or more, the contents of `dest` are indeterminate.

CONFORMS TO

SVID 3, BSD 4.3, ISO 9899

NOTES

The Linux C Library currently hasn't implemented the complete POSIX-collating.

In the POSIX or C locales `strxfrm()` is equivalent to copying the string with `strncpy()`.

swab

`swab`—Swaps adjacent bytes

SYNOPSIS

```
#include <string.h>
void swab(const void *from, void*to, size_t n);
```

DESCRIPTION

The `swab()` function copies `n` bytes from the array pointed to by `from` to the array pointed to by `to`, exchanging adjacent even and odd bytes. This function is used to exchange data between machines that have different low/high byte ordering.

RETURN VALUE

The `swab()` function returns no value.

CONFORMS TO

SVID 3, BSD 4.3

SEE ALSO

`bstring(3)`

GNU, 13 April 1993

sysconf

`sysconf`—Gets configuration information at runtime

SYNOPSIS

```
#include <unistd.h>
long sysconf(int name);
```

DESCRIPTION

`sysconf()` provides a way for the application to determine values for system limits or options at runtime.

The equivalent macros defined in `<unistd.h>` can only give conservative values; if an application wants to take advantage of values that may change, a call to `sysconf()` can be made, which may yield more liberal results.

For getting information about a particular file, see `fpathconf()` or `pathconf()`.

The following values are supported for `name`. First, the POSIX.1-compatible values:

<code>_SC_ARG_MAX</code>	The maximum length of the arguments to the <code>exec()</code> family of functions; the corresponding macro is <code>ARG_MAX</code> .
<code>_SC_CHILD_MAX</code>	The number of simultaneous processes per user ID; the corresponding macro is <code>_POSIX_CHILD_MAX</code> .
<code>_SC_CLK_TCK</code>	The number of clock ticks per second; the corresponding macro is <code>CLK_TCK</code> .
<code>_SC_STREAM_MAX</code>	The maximum number of streams that a process can have open at any time. The corresponding POSIX macro is <code>STREAM_MAX</code> ; the corresponding standard C macro is <code>FOPEN_MAX</code> .
<code>_SC_TZNAME_MAX</code>	The maximum number of bytes in a time zone name; the corresponding macro is <code>TZNAME_MAX</code> .
<code>_SC_OPEN_MAX</code>	The maximum number of files that a process can have open at any time; the corresponding macro is <code>_POSIX_OPEN_MAX</code> .
<code>_SC_JOB_CONTROL</code>	This indicates whether POSIX-style job control is supported, the corresponding macro is <code>_POSIX_JOB_CONTROL</code> .
<code>_SC_SAVED_IDS</code>	This indicates whether a process has a saved set-user-ID and a saved set-group-ID; the corresponding macro is <code>_POSIX_SAVED_IDS</code> .
<code>_SC_VERSION</code>	Indicates the year and month the POSIX.1 standard was approved in the format <code>YYMM</code> ; the value <code>199009L</code> indicates the most recent revision, 1990.

Next, the POSIX.2 values:

<code>_SC_BC_BASE_MAX</code>	Indicates the maximum obase value accepted by the <code>bc(1)</code> utility; the corresponding macro is <code>BC_BASE_MAX</code> .
<code>_SC_BC_DIM_MAX</code>	Indicates the maximum value of elements permitted in an array by <code>bc(1)</code> ; the corresponding macro is <code>BC_DIM_MAX</code> .
<code>_SC_BC_SCALE_MAX</code>	Indicates the maximum scale value allowed by <code>bc(1)</code> ; the corresponding macro is <code>BC_SCALE_MAX</code> .
<code>_SC_BC_STRING_MAX</code>	Indicates the maximum length of a string accepted by <code>bc(1)</code> ; the corresponding macro is <code>BC_STRING_MAX</code> .
<code>_SC_COLL_WEIGHTS_MAX</code>	Indicates the maximum numbers of weights that can be assigned to an entry of the <code>LC_COLLATE</code> order keyword in the locale definition file; the corresponding macro is <code>COLL_WEIGHTS_MAX</code> .
<code>_SC_EXPR_NEST_MAX</code>	Is the maximum number of expressions that can be nested within parentheses by <code>expr(1)</code> . The corresponding macro is <code>EXPR_NEST_MAX</code> .
<code>_SC_LINE_MAX</code>	The maximum length of a utility's input line length, either from standard input or from a file. This includes length for a trailing newline. The corresponding macro is <code>LINE_MAX</code> .
<code>_SC_RE_DUP_MAX</code>	The maximum number of repeated occurrences of a regular expression when the interval notation <code>\{m,n\}</code> is used. The value of the corresponding macro is <code>RE_DUP_MAX</code> .
<code>_SC_2_VERSION</code>	Indicates the version of the POSIX.2 standard in the format of <code>YYMM</code> . The corresponding macro is <code>POSIX2_VERSION</code> .
<code>_SC_2_DEV</code>	Indicates whether the POSIX.2 C language development facilities are supported. The corresponding macro is <code>POSIX2_C_DEV</code> .
<code>_SC_2_FORT_DEV</code>	Indicates whether the POSIX.2 FORTRAN development utilities are supported. The corresponding macro is <code>POSIX2_FORT_RUN</code> .
<code>_SC_2_FORT_RUN</code>	Indicates whether the POSIX.2 FORTRAN runtime utilities are supported. The corresponding macro is <code>POSIX2_FORT_RUN</code> .

POSIX2_LOCALEDEF

Indicates whether the POSIX.2 creation of locales via `locale(1)` is supported. The corresponding macro is `POSIX2_LOCALEDEF`.

_SC_2_SW_DEV

Indicates whether the POSIX.2 software development utilities option is supported. The corresponding macro is `POSIX2_SW_DEV`.

RETURN VALUE

The value returned is the value of the system resource, 1 if a queried option is available, 0 if it is not, or -1 on error. The variable `errno` is not set.

CONFORMS TO

POSIX.1, proposed POSIX.2

BUGS

It is difficult use `ARG_MAX` because it is not specified how much of the argument space for `exec()` is consumed by the user's environment variables.

Some returned values may be huge; they are not suitable for allocating memory.

POSIX.2 is not yet an approved standard; the information in this man page is subject to change.

closelog, openlog, syslog

closelog, openlog, syslog—Send messages to the system logger

SYNOPSIS

```
#include <syslog.h>
void openlog( char *ident, int option, int facility);
void syslog( int priority, char *format, ...);
void closelog( void );
```

DESCRIPTION

`closelog()` closes the descriptor being used to write to the system logger. The use of `closelog()` is optional.

`openlog()` opens a connection to the system logger for a program. The string pointed to by `ident` is added to each message, and is typically set to the program name. Values for `option` and `facility` are given in the next subsection. The use of `openlog()` is optional; it will automatically be called by `syslog()` if necessary, in which case `ident` will default to `NULL`.

`syslog()` generates a log message, which will be distributed by `syslogd(8)`. `priority` is a combination of the `facility` and the level, values for which are given in the next subsection. The remaining arguments are a `format`, as in `printf(3)` and any arguments required by the `format`, except that the two characters `%m` will be replaced by the error message string (`strerror`) corresponding to the present value of `errno`.

PARAMETERS

This section lists the parameters used to set the values of `option`, `facility`, and `priority`.

OPTION

The `option` argument to `openlog()` is an OR of any of these:

<code>LOG_CONS</code>	Write directly to system console if there is an error while sending to system logger
<code>LOG_NDELAY</code>	Open the connection immediately (normally, the connection is opened when the first message is logged)
<code>LOG_PERROR</code>	Print to <code>stderr</code> as well
<code>LOG_PID</code>	Include <code>PID</code> with each message

FACILITY

The `facility` argument is used to specify what type of program is logging the message. This lets the configuration file specify that messages from different facilities will be handled differently.

<code>LOG_AUTH</code>	Security/authorization messages (DEPRECATED use <code>LOG_AUTHPRIV</code> instead)
<code>LOG_AUTHPRIV</code>	Security/authorization messages (private)
<code>LOG_CRON</code>	Clock daemon (<code>cron</code> and <code>at</code>)
<code>LOG_DAEMON</code>	Other system daemons
<code>LOG_KERN</code>	Kernel messages
<code>LOG_LOCAL0</code> through <code>LOG_LOCAL7</code>	Reserved for local use
<code>LOG_LPR</code>	Line printer subsystem
<code>LOG_MAIL</code>	Mail subsystem
<code>LOG_NEWS</code>	Usenet news subsystem
<code>LOG_SYSLOG</code>	Messages generated internally by <code>syslogd</code>
<code>LOG_USER</code> (default)	Generic user-level messages
<code>LOG_UUCP</code>	UUCP subsystem

LEVEL

This determines the importance of the message. The levels, in order of decreasing importance, are

<code>LOG_EMERG</code>	System is unusable
<code>LOG_ALERT</code>	Action must be taken immediately
<code>LOG_CRIT</code>	Critical conditions
<code>LOG_ERR</code>	Error conditions
<code>LOG_WARNING</code>	Warning conditions
<code>LOG_NOTICE</code>	Normal, but significant, condition
<code>LOG_INFO</code>	Informational message
<code>LOG_DEBUG</code>	Debug-level message

HISTORY

A `syslog` function call appeared in BSD 4.2.

system

system—Executes a shell command

SYNOPSIS

```
#include <stdlib.h>
int system (const char * string);
```

DESCRIPTION

`system()` executes a command specified in `string` by calling `/bin/sh -c string`, and returns after the command has been completed. During execution of the command, `SIGCHLD` will be blocked, and `SIGINT` and `SIGQUIT` will be ignored.

RETURN VALUE

The value returned is 127 if the `execve()` call for `/bin/sh` fails, -1 if there was another error, and the return code of the command otherwise.

If the value of `string` is `NULL`, `system()` returns non-zero if the shell is available, and zero if not.

`system()` does not affect the wait status of any other children.

CONFORMS TO

ANSI C, POSIX.1, proposed POSIX.2, BSD 4.3

BUGS

Do not use `system()` from a program with `suid` or `sgid` privileges, because strange values for some environment variables might be used to subvert system integrity. Use the `exec(2)` family of functions instead, but not `exec1p(2)` or `execvp(2)`.

The check for the availability of `/bin/sh` is not actually performed; it is always assumed to be available.

It is possible for the shell command to return 127, so that code is not a sure indication that the `execve()` call failed; check `errno` to make sure.

telldir

`telldir`—Returns current location in directory stream

SYNOPSIS

```
#include <dirent.h>
off_t telldir(DIR *dir);
```

DESCRIPTION

The `telldir()` function returns the current location associated with the directory stream `dir`.

RETURN VALUE

The `telldir()` function returns the current location in the directory stream or `-1` if an error occurs.

ERRORS

`EBADF` Invalid directory stream descriptor `dir`

CONFORMS TO

BSD 4.3

31 March 1993

tempnam

tempnam—Creates a name for a temporary file

SYNOPSIS

```
#include <stdio.h>
char *tempnam(const char *dir, const char *pfx);
```

DESCRIPTION

The `tempnam()` function generates a unique temporary filename using up to five characters of `pfx`, if it is not `NULL`. The directory to place the file is searched for in the following order:

1. The directory specified by the environment variable `TMPDIR`, if it is writable
2. The directory specified by the argument `dir`, if it is not `NULL`
3. The directory specified by `P_tmpdir`
4. The directory `\tmp`

The storage for the filename is allocated by `malloc()`, and so can be freed by the function `free()`.

RETURN VALUE

The `tempnam()` function returns a pointer to the unique temporary filename, or `NULL` if a unique filename cannot be generated.

ERRORS

`EEXIST` Unable to generate a unique filename

CONFORMS TO

SVID 3, BSD 4.3

SEE ALSO

`mktemp(3)`, `mkstemp(3)`, `tmpnam(3)`, `tmpfile(3)`

termios, tcgetattr, tcsetattr, tcsendbreak, tcdrain, tcflush, tcflow, cfmakeraw, cfgetospeed, cfgetispeed, cfsetispeed, cfsetospeed, tcgetpgrp, tcsetpgrp

`termios, tcgetattr, tcsetattr, tcsendbreak, tcdrain, tcflush, tcflow, cfmakeraw, cfgetospeed, cfgetispeed, cfsetispeed, cfsetospeed, tcgetpgrp, tcsetpgrp`—Get and set terminal attributes, line control, get and set baud rate, get and set terminal foreground process group ID

SYNOPSIS

```
#include <termios.h>
#include <unistd.h>

int tcgetattr ( int fd, struct termios *termios_p );
int tcsetattr ( int fd,int optional_actions, struct termios *termios_p );
int tcsendbreak ( int fd,int duration );
int tcdrain ( int fd );
int tcflush ( int fd,int queue_selector );
```

```

int tcflow ( int fd,int action );
int cfmakeraw ( struct termios *termios_p );
speed_t cfgetospeed ( struct termios *termios_p );
int cfsetospeed ( struct termios *termios_p, speed_t speed );
speed_t cfgetispeed ( struct termios *termios_p );
int cfsetispeed ( struct termios *termios_p, speed_t speed );
pid_t tcgetpgrp ( int fd );
int tcsetpgrp ( int fd, pid_t pgrp id );

```

DESCRIPTION

The `termios` functions describe a general terminal interface that is provided to control asynchronous communications ports.

Many of the functions described here have a `termios_p` argument that is a pointer to a `termios` structure. This structure contains the following members:

```

tcflag_t c_iflag; /* input modes */
tcflag_t c_oflag; /* output modes */
tcflag_t c_cflag; /* control modes */
tcflag_t c_lflag; /*localmodes*/
cc_t c_cc[NCCS]; /* control chars */

```

The `c_iflag` flag constants are

IGNBRK	Ignore BREAK condition on input.
BRKINT	If IGNBRK is not set, generate SIGINT on BREAK condition, else read BREAK as character \0.
IGNPAR	Ignore framing errors and parity errors.
PARMRK	If IGNPAR is not set, prefix a character with a parity error or framing error with \377 \0. If neither IGNPAR nor PARMRK is set, read a character with a parity error or framing error as \0.
INPCK	Enable input parity checking.
ISTRIP	Strip off eighth bit.
INLCR	Translate NL to CR on input.
IGNCR	Ignore carriage return on input.
ICRNL	Translate carriage return to newline on input (unless IGNCR is set).
IUCLC	Map uppercase characters to lowercase on input.
IXON	Enable XON/XOFF flow control on output.
IXANY	Enable any character to restart output.
IXOFF	Enable XON/XOFF flow control on input.
IMAXBEL	Ring bell when input queue is full.

The `c_oflag` flag constants are

OPOST	Enable implementation-defined output processing.
OLCUC	Map lowercase characters to uppercase on output.
ONLCR	Map NL to CR-NL on output.
OCRNL	Map CR to NL on output.
ONOCR	Don't output CR at column 0.
ONLRET	Don't output CR.
OFILL	Send fill characters for a delay, rather than using a timed delay.
OFDEL	Fill character is ASCII DEL. If unset, fill character is ASCII NUL.
NLDLY	Newline delay mask. Values are NL0 and NL1.
CRDLY	Carriage return delay mask. Values are CR0, CR1, CR2,OR CR3.

termios, tgetattr, tcsetattr, tcsendbreak, tcdrain, tcf flush, tcflow, cfmakeraw, cfgetospeed, cfgetispeed, cfsetispeed, cfsetospeed, tcgetpgrp, tcsetpgrp

TABDLY	Horizontal tab delay mask. Values are TAB0, TAB1, TAB2, TAB3, or XTABS. A value of XTABS expands tabs to spaces (with tab stops every eight columns).
BSDLY	Backspace delay mask. Values are BS0 or BS1.
VTDLY	Vertical tab delay mask. Values are VT0 or VT1.
FFDLY	Form feed delay mask. Values are FF0 or FF1.

The `c_cflag` flag constants are

CSIZE	Character size mask. Values are CS5, CS6, CS7, or CS8.
CSTOPB	Set two stop bits, rather than one.
CREAD	Enable receiver.
PARENB	Enable parity generation on output and parity checking for input.
PARODD	Parity for input and output is odd.
HUPCL	Lower modem control lines after last process closes the device (hang up).
CLOCAL	Ignore modem control lines.
CIBAUD	Mask for input speeds (not used).
CRTSCTS	Flow control.

The `c_lflag` flag constants are

ISIG	When any of the characters INTR, QUIT, SUSP, or DSUSP are received, generate the corresponding signal.
ICANON	Enable canonical mode. This enables the special characters EOF, EOL, EOL2, ERASE, KILL, REPRINT, STATUS, and WERASE, and buffers by lines.
XCASE	If ICANON is also set, terminal is uppercase only. Input is converted to lowercase, except for characters preceded by \. On output, uppercase characters are preceded by \ and lowercase characters are converted to uppercase.
ECHO	echo input characters.
ECHOE	If ICANON is also set, the ERASE character erases the preceding input character, and WERASE erases the preceding word.
ECHOK	If ICANON is also set, the KILL character erases the current line.
ECHONL	If ICANON is also set, echo the NL character even if ECHO is not set.
ECHOCTL	If ECHO is also set, ASCII control signals other than TAB, NL, START, and STOP are echoed as ^X, where X is the character with ASCII code 0x10 greater than the control signal. For example, character 0x28 (BS) is echoed as ^H.
ECHOPRT	If ICANON and IECHO are also set, characters are printed as they are being erased.
ECHOKE	If ICANON is also set, KILL is echoed by erasing each character on the line, as specified by ECHOE and ECHOPRT.
FLUSHO	Output is being flushed. This flag is toggled by typing the DISCARD character.
NOFLSH	Disable flushing the input and output queues when generating the SIGINT and SIGQUIT signals, and flushing the input queue when generating the SIGSUSP signal.
TOSTOP	Send the SIGTTOU signal to the process group of a background process that tries to write to its controlling terminal.
PENDIN	All characters in the input queue are reprinted when the next character is read. (bash handles typeahead this way.)
IEXTEN	Enable implementation-defined input processing.

`tcsetattr()` gets the parameters associated with the object referred by `fd` and stores them in the `termios` structure referenced by `termios_p`. This function may be invoked from a background process; however, the terminal attributes may be subsequently changed by a foreground process.

`tcsetattr()` sets the parameters associated with the terminal (unless support is required from the underlying hardware that is not available) from the `termios` structure referred to by `termios_p`. `optional_actions` specifies when the changes take effect:

<code>TCSANOW</code>	The change occurs immediately.
<code>TCSADRAIN</code>	The change occurs after all output written to <code>fd</code> has been transmitted. This function should be used when changing parameters that affect output.
<code>TCSAFLUSH</code>	The change occurs after all output written to the object referred by <code>fd</code> has been transmitted, and all input that has been received but not read will be discarded before the change is made.

`tcsendbreak()` transmits a continuous stream of zero-valued bits for a specific duration, if the terminal is using asynchronous serial data transmission. If `duration` is zero, it transmits zero-valued bits for at least 0.25 seconds, and not more than 0.5 seconds. If `duration` is not zero, it sends zero-valued bits for `duration*N` seconds, where `N` is at least 0.25, and not more than 0.5.

If the terminal is not using asynchronous serial data transmission, `tcsendbreak()` returns without taking any action.

`tcdrain()` waits until all output written to the object referred to by `fd` has been transmitted.

`tcflush()` discards data written to the object referred to by `fd` but not transmitted, or data received but not read, depending on the value of `queue_selector`:

<code>TCIFLUSH</code>	Flushes data received but not read
<code>TCOFLUSH</code>	Flushes data written but not transmitted
<code>TCIOFLUSH</code>	Flushes both data received but not read, and data written but not transmitted

`tcflow()` suspends transmission or reception of data on the object referred to by `fd`, depending on the value of `action`:

<code>TCOOFF</code>	Suspends output
<code>TCOON</code>	Restarts suspended output
<code>TCIOFF</code>	Transmits a <code>STOP</code> character, which stops the terminal device from transmitting data to the system
<code>TCION</code>	Transmits a <code>START</code> character, which starts the terminal device transmitting data to the system

The default on open of a terminal file is that neither its input nor its output is suspended.

The baud rate functions are provided for getting and setting the values of the input and output baud rates in the `termios` structure. The new values do not take effect until `tcsetattr()` is successfully called.

Setting the speed to `B0` instructs the modem to hang up. The actual bit rate corresponding to `B38400` may be altered with `setserial(8)`.

The input and output baud rates are stored in the `termios` structure.

`cfmakeraw` sets the terminal attributes as follows:

```
termios_p->c_iflag &= ~(IGNBRK|BRKINT|PARMRK|ISTRIP
|INLCR|IGNCR|ICRNL|IXON);
termios_p->c_oflag &= ~OPOST;
termios_p->c_lflag &= ~(ECHO|ECHONL|ICANON|ISIG|IEXTEN);
termios_p->c_cflag &= ~(CSIZE|PARENB);
termios_p->c_cflag |= CS8;
```

`cfgetospeed()` returns the output baud rate stored in the `termios` structure pointed to by `termios_p`.

`cfsetospeed()` sets the output baud rate stored in the `termios` structure pointed to by `termios_p` to speed, which must be one of these constants:

```
B0
B50
B75
```

```

B110
B134
B150
B200
B300
B600
B1200
B1800
B2400
B4800
B9600
B19200
B38400
B57600
B115200
B230400

```

The zero baud rate, `B0`, is used to terminate the connection. If `B0` is specified, the modem control lines shall no longer be asserted. Normally, this will disconnect the line. `CBAUDEX` is a mask for the speeds beyond those defined in POSIX.1 (57600 and above). Thus, `B57600 & CBAUDEX` is non-zero.

`cfgetispeed()` returns the input baud rate stored in the `termios` structure.

`cfsetispeed()` sets the input baud rate stored in the `termios` structure to `speed`. If the input baud rate is set to zero, the input baud rate will be equal to the output baud rate.

`tcgetpgrp()` returns process group ID of foreground processing group, or `-1` on error.

`tcsetpgrp()` sets process group ID to `pgrp`. `pgrp` must be the ID of a process group in the same session.

RETURN VALUES

`cfgetispeed()` returns the input baud rate stored in the `termios` structure.

`cfgetospeed()` returns the output baud rate stored in the `termios` structure.

`tcgetpgrp()` returns process group ID of foreground processing group, or `-1` on error.

All other functions return

<code>0</code>	On success
<code>-1</code>	On failure and set <code>errno</code> to indicate the error

tmpfile

tmpfile—Creates a temporary file

SYNOPSIS

```

#include <stdio.h>
FILE *tmpfile (void);

```

DESCRIPTION

The `tmpfile()` function generates a unique temporary filename using the path prefix `P_tmpdir` defined in `<stdio.h>`. The temporary file is then opened in binary read/write (`w+b`) mode. The file will be automatically deleted when it is closed or the program terminates.

RETURN VALUE

The `tmpfile()` function returns a stream descriptor, or `NULL` if a unique filename cannot be generated or the unique file cannot be opened.

ERRORS

<code>EACCES</code>	Search permission denied for directory in file's path prefix
<code>EEXIST</code>	Unable to generate a unique filename
<code>EMFILE</code>	Too many file descriptors in use by process
<code>ENFILE</code>	Too many files open in system
<code>EROFS</code>	Read-only filesystem

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

`mktemp(3)`, `mkstemp(3)`, `tmpnam(3)`, `tmpnam(3)`

GNU, 3 April 1993

tmpnam

`tmpnam`—Creates a name for a temporary file

SYNOPSIS

```
#include <stdio.h>
char *tmpnam(char *s);
```

DESCRIPTION

The `tmpnam()` function generates a unique temporary filename using the path prefix `P_tmpdir` defined in `<stdio.h>`. If the argument `s` is `NULL`, `tmpnam()` returns the address of an internal static area that holds the filename, which is overwritten by subsequent calls to `tmpnam()`. If `s` is not `NULL`, the filename is returned in `s`.

RETURN VALUE

The `tmpnam()` function returns a pointer to the unique temporary filename, or `NULL` if a unique name cannot be generated.

ERRORS

<code>EEXIST</code>	Unable to generate a unique filename
---------------------	--------------------------------------

CONFORMS TO

SVID 3, POSIX, BSD 4.3, ISO 9899

toascii

toascii—Converts character to ASCII

SYNOPSIS

```
#include <ctype.h>
int toascii (int c);
```

DESCRIPTION

toascii() converts *c* to a 7-bit unsigned char value that fits into the ASCII character set, by clearing the high-order bits.

RETURN VALUE

The value returned is that of the converted character.

CONFORMS TO

SVID, BSD

BUGS

Many people will be unhappy if you use this function. This function will convert accented letters into random characters.

SEE ALSO

isascii(3), toupper(3), tolower(3)

GNU, 16 September 1995

toupper, tolower

toupper, tolower—Convert letter to uppercase or lowercase

SYNOPSIS

```
#include <ctype.h>
int toupper (int c);
int tolower (int c);
```

DESCRIPTION

toupper() converts the letter *c* to uppercase, if possible.

tolower() converts the letter *c* to lowercase, if possible.

RETURN VALUE

The value returned is that of the converted letter, or *c* if the conversion was not possible.

CONFORMS TO

ANSI C, BSD 4.3

BUGS

The details of what constitutes an uppercase or lowercase letter depend on the current locale. For example, the default locale does not know about umlauts, so no conversion is done for them.

In some non-English locales, there are lowercase letters with no corresponding uppercase equivalent; the German sharp *s* is one example.

tsearch, tfind, tdelete, twalk

tsearch, tfind, tdelete, twalk—Manage a binary tree

SYNOPSIS

```
#include <search.h>
void *tsearch (const void *key, void **rootp,
int (*compar)(const void *, const void *));
void *tfind (const void *key, const void **rootp,
int (*compar)(const void *, const void *));
void *tdelete (const void *key, void**rootp,
int (*compar)(const void *, const void *));
void twalk (const void *root, void (*action)(const void*nodep,
const VISIT which,
const int depth));
```

DESCRIPTION

tsearch, tfind, twalk, and tdelete manage a binary tree. They are generalized from Knuth (6.2.2) Algorithm T. The first field in each node of the tree is a pointer to the corresponding data item. (The calling program must store the actual data.) compar points to a comparison routine, which takes pointers to two items. It should return an integer that is negative, zero, or positive, depending on whether the first item is less than, equal to, or greater than the second.

tsearch searches the tree for an item. key points to the item to be searched for. rootp points to a variable that points to the root of the tree. If the tree is empty, then the variable that rootp points to should be set to NULL. If the item is found in the tree, then tsearch returns a pointer to it. If it is not found, then tsearch adds it, and returns a pointer to the newly added item.

tfind is like tsearch, except that if the item is not found, then tfind returns NULL.

tdelete deletes an item from the tree. Its arguments are the same as for tsearch.

twalk performs depth-first, left-to-right traversal of a binary tree. root points to the starting node for the traversal. If that node is not the root, then only part of the tree will be visited. twalk calls the user function action each time a node is visited (that is, three times for an internal node, and once for a leaf). action, in turn, takes three arguments. The first is a pointer to the node being visited. The second is an integer that takes on the values preorder, postorder, and endorder depending on whether this is the first, second, or third visit to the internal node, or leaf if it is the single visit to a leaf node. (These symbols are defined in <search.h>.) The third argument is the depth of the node, with zero being the root.

RETURN VALUE

tsearch returns a pointer to a matching item in the tree, or to the newly added item, or NULL if there was insufficient memory to add the item. tfind returns a pointer to the item, or NULL if no match is found. If there are multiple elements that match the key, the element returned is unspecified.

tdelete returns a pointer to the parent of the item deleted, or NULL if the item was not found.

tsearch, tfind, and tdelete also return NULL if rootp was NULL on entry.

WARNINGS

twalk takes a pointer to the root, while the other functions take a pointer to a variable that points to the root.

twalk uses postorder to mean “after the left subtree, but before the right subtree.” Some authorities would call this inorder, and reserve postorder to mean “after both subtrees.”

`tdelete` frees the memory required for the node in the tree. The user is responsible for freeing the memory for the corresponding data.

The example program depends on the fact that `twalk` makes no further reference to a node after calling the user function with argument `endorder` or `leaf`. This works with the GNU library implementation, but is not in the SysV documentation.

EXAMPLE

The following program inserts twelve random numbers into a binary tree, then prints the numbers in order. The numbers are removed from the tree and their storage freed during the traversal.

```
#include <search.h>
#include <stdlib.h>
#include <stdio.h>

void *root=NULL;

void *xmalloc(unsigned n)
{
    void *p;
    p = malloc(n);
    if(p) return p;
    fprintf(stderr, "insufficient memory\n");
    exit(1);
}

int compare(const void *pa, const void *pb)
{
    if(*(int *)pa < *(int *)pb) return -1;
    if(*(int *)pa > *(int *)pb) return 1;
    return 0;
}

void action(const void *nodep, const VISIT which, const int depth)
{
    int *datap;
    void *val;

    switch(which)
    {
        case preorder:
            break;
        case postorder:
            datap = *(int **)nodep;
            printf("%6d\n", *datap);
            break;
        case endorder:
            datap = *(int **)nodep;
            (void)tdelete(datap, &root, compare);
            free(datap);
            break;
        case leaf:
            datap = *(int **)nodep;
            printf("%6d\n", *datap);
            val = tdelete(datap, &root, compare);
            free(datap);
            break;
    }
    return;
}
```

```

    }

int main()
{
    int i, *ptr;
    void *val;

    for (i = 0; i < 12; i++)
    {
        ptr = (int *)xmalloc(sizeof(int));
        *ptr = rand() & 0xff;
        val = tsearch((void *)ptr, &root, compare);
        if (val == NULL) exit(1);
    }
    twalk(root, action);
    return 0;
}

tzset

tzset—Initializes time conversion information

SYNOPSIS

```

#include <time.h>
void tzset (void);
extern char *tzname[2];

```

DESCRIPTION

The `tzset()` function initializes the `tzname` variable from the `TZ` environment variable. This function is automatically called by the other time conversion functions that depend on the time zone.

If the `TZ` variable does not appear in the environment, the `tzname` variable is initialized with the best approximation of local wall clock time, as specified by the `tzfile(5)`-format file `/usr/lib/zoneinfo/localtime`.

If the `TZ` variable does appear in the environment but its value is `NULL` or its value cannot be interpreted using any of the formats specified in the following paragraphs, Coordinated Universal Time (UTC) is used.

The value of `TZ` can be one of three formats. The first format is used when there is no daylight saving time in the local time zone:

```
std offset
```

The `std` string specifies the name of the time zone and must be three or more alphabetic characters. The `offset` string immediately follows `std` and specifies the time value to be added to the local time to get Coordinated Universal Time (UTC). The `offset` is positive if the local time zone is west of the Prime Meridian and negative if it is east. The hour must be between 0 and 24, and the minutes and seconds 0 and 59.

The second format is used when there is daylight saving time:

```
std offset dst [offset],start[/time],end[/time]
```

There are no spaces in the specification. The initial `std` and `offset` specify the standard time zone, as described. The `dst` string and `offset` specify the name and offset for the corresponding daylight savings time zone. If the `offset` is omitted, it defaults to one hour ahead of standard time.

The `start` field specifies when Daylight Savings Time goes into effect and the `end` field specifies when the change is made back to Standard Time. These fields may have the following formats:

<code>Jn</code>	This specifies the Julian day with n between 1 and 365. February 29 is never counted even in leap years.
<code>n</code>	This specifies the Julian day with n between 1 and 365. February 29 is counted in leap years.
<code>Mm. w. d</code>	This specifies day d ($0 \leq d \leq 6$) of week w ($1 \leq w \leq 5$) of month m ($1 \leq m \leq 12$). Week 1 is the first week in which day d occurs and week 5 is the last week in which day d occurs. Day 0 is a Sunday.

The time fields specify when, in the local time currently in effect, the change to the other time occurs. If omitted, the default is `02:00:00`.

The third format specifies that the time zone information should be read from a file:

```
:[filespec]
```

If the file specification `filespec` is omitted, the time zone information is read from `/usr/lib/zoneinfo/localtime`, which is in `tzfile(5)` format. If `filespec` is given, it specifies an-other `tzfile(5)`-format file to read the time zone information from. If `filespec` does not begin with a `/`, the file specification is relative to the system time conversion information directory `/usr/lib/zoneinfo`.

none

none—Undocumented library functions

SYNOPSIS

Undocumented library functions

DESCRIPTION

This man page mentions those library functions that are implemented in the standard libraries but not yet documented in man pages.

SOLICITATION

If you have information about these functions, please look in the source code, write a man page (using a style similar to that of the other Linux section 3 man pages), and send it to aeb@cw1.n1 for inclusion in the next man page release.

THE LIST

des_setparity, dn_skipname, ecb_crypt, encrypt, endnetgrent, endrprcent, endutent, execlp, fcrypt, fp_nquery, fp_query, fp_resstat, get_myaddress, getnetgrent, getnetname, getopt_long_only, getpublickey, getrpcbyname, getrpcbynumber, getrpccent, getrpcport, getsecretkey, getutid, getutline, h_errlist, host2netname, hostalias, inet_nsap_addr, inet_nsap_ntoa_init_des, inetngr, key_decryptsession, key_encryptsession, key_gendes, key_setsecret, lfind, libc_nls_init, lockf, lsearch, mcheck, memalign, mstats, mtrace, netname2host, netname2user, nlist, obstack_free, p_cdname, p_cdname, p_class, p_fname, p_option, p_query, p_rr, p_time, p_type, passwd2des, pmap_getmaps, pmap_getport, pmap_rmtcall, pmap_set, pmap_unset, putlong, putshort, pututline, rcmd, re_compile_fastmap, re_compile_pattern, re_match, re_match_2, re_rx_search, re_search, re_search_2, re_set_registers, re_set_syntax, registerrpc, res_send_setqhook, res_send_setrhook, rexec, rresvport, rtime, ruserok, ruserpass, setfileno, sethostfile, setkey, setlogmask, setnetgrent, setrprcent, setutent, siglongjmp, snprintf, stpcpy, svc_exit, svc_getreq, svc_getreqset, svc_register, svc_run, svc_sendreply, svc_unregister, svcerr_auth, svcerr_decode, svcerr_noproc, svcerr_noprogram, svcerr_progvers, svcerr_systemerr, svcerr_weakauth, svcd_create, svc_create, svctcp_create, svcudp_bufcreate, svcudp_create, svcudp_enablecachesyscall, tdelete, tell, tfind, timegm, tr_break, tsearch, twalk, tzsetwall, ufc_dofinalperm, ufc_doit, user2netname, utmpname, valloc, vsnprintf, vsyslog, xdecrypt, xdr_accepted_reply, xdr_array, xdr_authdes_cred, xdr_authdes_verf, xdr_authunix_parms, xdr_bool, xdr_bytes, xdr_callhdr, xdr_callmsg, xdr_char, xdr_cryptkeyarg, xdr_cryptkeyres, xdr_datum, xdr_des_block, xdr_domainname, xdr_double, xdr_enum, xdr_float, xdr_free, xdr_getcredres, xdr_int, xdr_keybuf, xdr_keystatus, xdr_long, xdr_mapname, xdr_netnamestr, xdr_netobj, xdr_opaque, xdr_opaque_auth, xdr_passwd, xdr_peername, xdr_pmap, xdr_pmaplist, xdr_pointer, xdr_reference, xdr_rejected_reply, xdr_replymsg, xdr_rmtcall_args, xdr_rmtcallres, xdr_short, xdr_string, xdr_u_char, xdr_u_int, xdr_u_long, xdr_u_short, xdr_union, xdr_unixcred, xdr_vector, xdr_void, xdr_wrapstring, xdr_yyp_buf, xdr_yyp_inaddr, xdr_yypbind_binding, xdr_yypbind_resp, xdr_yypbind_resptype, xdr_yypbind_setdom, xdr_yypdelete_args, xdr_yypmaplist, xdr_yypmaplist_str, xdr_yypasswd, xdr_yypreq_key, xdr_yypreq_nokey, xdr_yypresp_all, xdr_yypresp_all_seq, xdr_yypresp_key_val, xdr_yypresp_maplist, xdr_yypresp_master, xdr_yypresp_order, xdr_yypresp_val, xdr_yypstat, xdr_yypupdate_args, xdrmem_create, xdrrec_create, xdrrec_endofrecord, xdrrec_eof, xdrrec_skiprecord, xdrstdio_create, xencrypt, xprt_register, xprt_unregister, yp_all, yp_bind, yp_first, yp_get_default_domain, yp_maplist, yp_master, yp_match, yp_next, yp_order, yp_unbind, yp_update, yperr_string, ypprot_err

usleep

`usleep`—Suspend execution for interval of microseconds

SYNOPSIS

```
#include <unistd.h>
void usleep(unsigned long usec);
```

DESCRIPTION

The `usleep()` function suspends execution of the calling process for `usec` microseconds. The sleep may be lengthened slightly by any system activity or by the time spent processing the call.

CONFORMS TO

BSD 4.3

SEE ALSO

wcstombs

`wcstombs`—Converts a wide character string to a multibyte character string

SYNOPSIS

```
#include <stdlib.h>
size_t wcstombs(char *s, const wchar_t *pwcs, size_t n);
```

DESCRIPTION

The `wcstombs()` function converts a sequence of wide characters from the array `pwcs` into a sequence of multibyte characters and stores up to `n` bytes of multibyte characters in the array `s`.

RETURN VALUE

`wcstombs()` returns the number of bytes stored in `s` or `-1` if `s` contains an invalid wide character.

wctomb

`wctomb`—Converts a wide character to a multibyte character

SYNOPSIS

```
#include <stdlib.h>
int wctomb(char *s, wchar_t wchar);
```

DESCRIPTION

The `wctomb()` function converts a wide character `wchar` into a multibyte character and, if `s` is not `NULL`, stores the multibyte character representation in `s`.

RETURN VALUE

`wctomb()` returns the number of bytes in the multibyte character or `-1` if the wide character is not valid.

charsets

charsets—Programmer's view of character sets and internationalization

DESCRIPTION

Linux is an international operating system. Several of its utilities and device drivers (including the console driver) support multilingual character sets including Latin-alphabet letters with diacritical marks, accents, ligatures, and entire non-Latin alphabets including Greek, Cyrillic, Arabic, and Hebrew.

This manual page presents a programmer's-eye view of different character-set standards and how they fit together on Linux. Standards discussed include ASCII, ISO 8859, KOI8-R, Unicode, ISO 2022, and ISO 4873.

ASCII

ASCII (American Standard Code for Information) is the original 7-bit character set, originally designed for American English. It is currently described by the ECMA-6 standard.

An ASCII variant replacing the American crosshatch/octothorpe/hash pound symbol with the British pound-sterling symbol is used in Great Britain; when needed, the American and British variants may be distinguished as U.S. ASCII and U.K. ASCII.

As Linux was written for hardware designed in the United States, it natively supports U.S. ASCII.

ISO 8859

ISO 8859 is a series of 10 8-bit character sets, all of which have U.S. ASCII in their low (7-bit) half, invisible control characters in positions 128 to 159, and 96 fixed-width graphics in positions 160-255.

Of these, the most important is ISO 8859-1 (Latin-1). It is natively supported in the Linux console driver, fairly well supported in X11R6, and is the base character set of HTML.

Console support for the other 8859 character sets is available under Linux through user-mode utilities (such as `setfont(8)`) that modify keyboard bindings and the EGA graphics table and employ the "user mapping" font table in the console driver.

Here are brief descriptions of each set:

- | | |
|------------------|---|
| 8859-1 (Latin-1) | Latin-1 covers most Western European languages such as Albanian, Catalan, Danish, Dutch, English, Faroese, Finnish, French, German, Galician, Irish, Icelandic, Italian, Norwegian, Portuguese, Spanish, and Swedish. The lack of the ligatures Dutch <i>jj</i> , French <i>oe</i> , and old-style German quotation marks is tolerable. |
| 8859-2 (Latin-2) | Latin-2 supports most Latin-written Slavic and Central European languages: Czech, German, Hungarian, Polish, Rumanian, Croatian, Slovak, and Slovene. |
| 8859-3 (Latin-3) | Latin-3 is popular with authors of Esperanto, Galician, Maltese, and Turkish. |
| 8859-4 (Latin-4) | Latin-4 introduced letters for Estonian, Latvian, and Lithuanian. It is essentially obsolete; see 8859-10 (Latin-6). |

8859-5	Cyrillic letters supporting Bulgarian, Byelorussian, Macedonian, Russian, Serbian, and Ukrainian. Ukrainians read the letter <i>ghe</i> with downstroke as <i>heh</i> and would need a <i>ghe</i> with upstroke to write a correct <i>ghe</i> . (See the discussion of KOI8-R in the next subsection.)
8859-6	Supports Arabic. The 8859-6 glyph table is a fixed font of separate letter forms, but a proper display engine should combine them pairwise into initial, medial, and final forms.
8859-7	Supports modern Greek.
8859-8	Supports Hebrew.
8859-9 (Latin-5)	This is a variant of Latin-1 that replaces rarely used Icelandic letters with Turkish ones.
8859-10 (Latin-6)	Latin-6 adds the last Inuit (Greenlandic) and Sami (Lappish) letters that were missing in Latin 4 to cover the entire Nordic area. RFC 1345 listed a preliminary and different Latin 6. Skolt Sami still needs a few more accents than these.

KOI8-R

KOI8-R is a non-ISO character set popular in Russia. The lower half is U.S. ASCII; the upper is a Cyrillic character set somewhat better designed than ISO 8859-5.

Console support for KOI8-R is available under Linux through user-mode utilities that modify keyboard bindings and the EGA graphics table, and that employ the “user mapping” font table in the console driver.

UNICODE

Unicode (ISO 10646) is a standard that aims to unambiguously represent every known glyph in every human language. Unicode’s native encoding is 32-bit (older versions used 16 bits). Information on Unicode is available at <http://www.unicode.com>.

Linux represents Unicode using the 8-bit Unicode Transfer Format (UTF-8). UTF-8 is a variable length encoding of Unicode. It uses 1 byte to code 7 bits, 2 bytes for 11 bits, 3 bytes for 16 bits, 4 bytes for 21 bits, 5 bytes for 26 bits, and 6 bytes for 31 bits.

Let 0, 1, x stand for a zero, one, or arbitrary bit. A byte 0xxxxxxx stands for the Unicode 00000000 0xxxxxxx, which codes the same symbol as the ASCII 0xxxxxxx. Thus, ASCII goes unchanged into UTF-8, and people using only ASCII do not notice any change—not in code, and not in file size.

A byte 110xxxxx is the start of a 2-byte code, and 110xxxxx 10yyyyyy is assembled into 00000xxx xyyyyyyy. A byte 1110xxxx is the start of a 3-byte code, and 1110xxxx 10yyyyyy 10zzzzzz is assembled into xxxxyyyy yzzzzzzz. (When UTF-8 is used to code the 31-bit ISO 10646, then this progression continues up to 6-byte codes.)

For ISO-8859-1 users this means that the characters with high bit set now are coded with two bytes. This tends to expand ordinary text files by one or two percent. There are no conversion problems, however, since the Unicode value of ISO-8859-1 symbols equals their ISO-8859-1 value (extended by eight leading zero bits). For Japanese users, this means that the 16-bit codes now in common use will take three bytes, and extensive mapping tables are required. Many Japanese therefore prefer ISO 2022.

Note that UTF-8 is self-synchronizing: 10xxxxxx is a tail, any other byte is the head of a code. Note that the only way ASCII bytes occur in a UTF-8 stream is as themselves. In particular, there are no embedded NULs or /s that form part of some larger code.

Because ASCII, and, in particular, NUL and /, are unchanged, the kernel does not notice that UTF-8 is being used. It does not care at all what the bytes it is handling stand for.

Rendering of Unicode data streams is typically handled through subfont tables that map a subset of Unicode to glyphs. Internally, the kernel uses Unicode to describe the subfont loaded in video RAM. This means that in UTF-8 mode one can use a character set with 512 different symbols. This is not enough for Japanese, Chinese, and Korean, but it is enough for most other purposes.

ISO 2022 AND ISO 4873

The ISO 2022 and 4873 standards describe a font-control model based on VT100 practice. This model is (partially) supported by the Linux kernel and by `xterm(1)`. It is popular in Japan and Korea.

There are four graphic character sets, called G0, G1, G2, and G3, and one of them is the current character set for codes with high bit zero (initially G0), and one of them is the current character set for codes with high bit one (initially G1). Each graphic character set has 94 or 96 characters, and is essentially a 7-bit character set. It uses codes either 040–0177 (041–0176) or 0240–0377 (0241–0376). G0 always has size 94 and uses codes 041–0176.

Switching between character sets is done using the shift functions `^N` (S0 or LS1), `^O` (S1 or LS0), `ESC n` (LS2), `ESC o` (LS3), `ESC N` (SS2),

`ESC 0` (SS3), `ESC ^` (LS1R), `ESC }` (LS2R), `ESC |` (LS3R). The function `LSn` makes character set `Gn` the current one for codes with high bit zero. The function `LSnR` makes character set `Gn` the current one for codes with high bit one. The function `SSn` makes character set `Gn` ($n=2$ or 3) the current one for the next character only (regardless of the value of its high order bit).

A 94-character set is designated as `Gn` character set by an escape sequence `ESC (xx` (for G0), `ESC) xx` (for G1), `ESC * xx` (for G2), `ESC + xx` (for G3), where `xx` is a symbol or a pair of symbols found in the ISO 2375 International Register of Coded Character Sets. For example, `ESC (@` selects the ISO 646 character set as G0, `ESC (A` selects the U.K. standard character set (with pound instead of number sign), `ESC (B` selects ASCII (with dollar instead of currency sign), `ESC (M` selects a character set for African languages, `ESC (! A` selects the Cuban character set, and so on.

A 96-character set is designated as `Gn` character set by an escape sequence `ESC - xx` (for G1), `ESC . xx` (for G2) or `ESC / xx` (for G3). For example, `ESC - G` selects the Hebrew alphabet as G1.

A multibyte character set is designated as `Gn` character set by an escape sequence `ESC $ xx` or `ESC $ (xx` (for G0), `ESC $) xx` (for G1), `ESC $ * xx` (for G2), `ESC $ + xx` (for G3). For example, `ESC $ (C` selects the Korean character set for G0. The Japanese character set selected by `ESC $ B` has a more recent version selected by `ESC & @ESC $ B`.

ISO 4873 stipulates a narrower use of character sets, where G0 is fixed (always ASCII), so that G1, G2, and G3 can only be invoked for codes with the high order bit set. In particular, `^N` and `^O` are not used anymore, `ESC (xx` can be used only with `xx=B`, and `ESC) xx`, `ESC * xx`, `ESC + xx` are equivalent to `ESC - xx`, `ESC . xx`, and `ESC / xx`, respectively.

console

`console`—Console terminal and virtual consoles

DESCRIPTION

A Linux system has up to 63 *virtual consoles* (character devices with major number 4 and minor number 1 to 63), usually called `/dev/ttyn` with `n` 63. The current console is also addressed by `/dev/console` or `/dev/tty0`, the character device with major number 4 and minor number 0. The device files `/dev/*` are usually created using the script `MAKEDEV`, or using `mknod(1)`, usually with mode `0622` and owner `root.tty`.

Before kernel version 1.1.54, the number of virtual consoles was compiled into the kernel (in `tty.h`: `#define NR_CONSOLES 8`) and could be changed by editing and recompiling because version 1.1.54 virtual consoles are created on-the-fly, as soon as they are needed.

Common ways to start a process on a console are the following:

- Tell `init(8)` (in `inittab(5)`) to start a `getty(8)` on the console
- Ask `open(1)` to start a process on the console
- Start `x`; it will find the first unused console and display its output there. (There is also the ancient `doshell(8)`.)

Common ways to switch consoles are the following:

- Use Alt+Fn or Ctrl+Alt+Fn to switch to console n; AltGr+Fn might bring you to console n+12 [here Alt and AltGr refer to the left and right Alt keys, respectively]
- Use Alt+RightArrow or Alt+LeftArrow to cycle through the presently allocated consoles
- Use the program `chvt(1)`. (The key mapping can be set by the user; see `loadkeys(1)`; the preceding key combinations are according to the default settings.)

The command `disalloc(8)` will free the memory taken by the screen buffers for consoles that no longer have any associated process.

PROPERTIES

Consoles carry a lot of state. I hope to document that some other time. The most important fact is that the consoles simulate vt100 terminals. In particular, a console is reset to the initial state by printing the two characters ESC c. All escape sequences can be found in `console_codes(4)`.

FILES

```
/dev/console  
/dev/tty*

console_codes

console_codes—Linux console escape and control sequences

DESCRIPTION

The Linux console implements a large subset of the VT102 and ECMA-48/ISO 6429/ANSI X3.64 terminal controls, plus certain private-mode sequences for changing the color palette, character-set mapping, and so on. In the following tabular descriptions, the second column gives ECMA-48 or DEC mnemonics (the latter if prefixed with DEC) for the given function. Sequences without a mnemonic are neither ECMA-48 nor VT102.

After all the normal output processing has been done, and a stream of characters arrives at the console driver for actual printing, the first thing that happens is a translation from the code used for processing to the code used for printing.

If the console is in UTF-8 mode, then the incoming bytes are first assembled into 16-bit Unicode codes. Otherwise, each byte is transformed according to the current mapping table (which translates it to a Unicode value). (See the “Character Sets” subsection for discussion.)

In the normal case, the Unicode value is converted to a font index, and this is stored in video memory, so that the corresponding glyph (as found in video ROM) appears on the screen. Note that the use of Unicode (and the design of the PC hardware) allows the use of 512 different glyphs simultaneously.

If the current Unicode value is a control character, or you are currently processing an escape sequence, the value will be treated specially. Instead of being turned into a font index and rendered as a glyph, it may trigger cursor movement or other control functions. (See the “Linux Console Controls” subsection.)

It is generally not good practice to hardwire terminal controls into programs. Linux supports a `terminfo(5)` database of terminal capabilities. Rather than emitting console escape sequences by hand, you will almost always want to use a `terminfo`-aware screen library or utility such as `ncurses(3)`, `tput(1)`, or `reset(1)`.

LINUX CONSOLE CONTROLS

This section describes all the control characters and escape sequences that invoke special functions (that is, anything other than writing a glyph at the current cursor location) on the Linux console.

CONTROL CHARACTERS

A character is a control character if (before transformation according to the mapping table) it has one of the 14 codes 00 (NUL), 07 (BEL), 08 (BS), 09 (HT), 0a (LF), 0b (VT), 0c (FF), 0d (CR), 0e (SO), 0f (SI), 18 (CAN), 1a (SUB), 1b (ESC), 7f (DEL). One can set a display control characters mode (see below), and allow 07, 09, 0b, 18, 1a, 7f to be displayed as glyphs. On the other hand, in UTF-8 mode all codes 00–1f are regarded as control characters, regardless of any display control characters mode.

If you have a control character, it is acted upon immediately and then discarded (even in the middle of an escape sequence) and the escape sequence continues with the next character. (However, ESC starts a new escape sequence, possibly aborting a previous unfinished one, and CAN and SUB abort any escape sequence.) The recognized control characters are BEL, BS, HT, LF, VT, FF, CR, SO, SI, CAN, SUB, ESC, DEL, CSI. They do what one would expect:

BEL (0x07, ^G) beeps.

BS (0x08, ^H) backspaces one column (but not past the beginning of the line).

HT (0x09, ^I) goes to the next tab stop or to the end of the line if there is no earlier tab stop.

LF (0x0A, ^J), VT (0x0B, ^K) and FF (0x0C, ^L) all give a linefeed.

CR (0x0D, ^M) gives a carriage return.

SO (0x0E, ^N) activates the G1 character set, and if LF/NL (new line mode) is set, also a carriage return.

SI (0x0F, ^O) activates the G0 character set.

CAN (0x18, ^X) and SUB (0x1A, ^Z) interrupt escape sequences.

ESC (0x1B, ^[) starts an escape sequence.

DEL (0x7F) is ignored.

CSI (0x9B) is equivalent to ESC [.

ESC SEQUENCES, NOT CSI SEQUENCES

ESC c	RIS	Reset.
ESC D	IND	Linefeed.
ESC E	NEL	Newline.
ESC H	HTS	Set tab stop at current column.
ESC M	RI	Reverse linefeed.
ESC Z	DECID	DEC private identification. The kernel returns the string ESC [? 6 c, claiming that it is a VT102.
ESC 7	DECSG	Save current state (cursor coordinates, attributes, character sets).
ESC 8	DECRG	Restore most recently saved state.
ESC [CSI	Control sequence introducer.
ESC %		Start sequence selecting character set.
ESC % e		Select default (ISO 646 / ISO 8859-1).
ESC % G		Select UTF-8.
ESC % 8		Select UTF-8 (obsolete).
ESC # 8	DECALN	DEC screen alignment test: fill screen with Es.
ESC (Start sequence defining G0 character set.
ESC (B		Select default (ISO 8859-1 mapping).
ESC (0		Select vt100 graphics mapping.

ESC (U		Select null mapping—straight to character ROM.
ESC (K		Select user mapping, the map that is loaded by the utility <code>mapscrn(8)</code> .
ESC)		Start sequence defining G1 (followed by one of B, 0, U, K, as above).
ESC >	DECPNM	Set numeric keypad mode.
ESC =	DECPAM	Set application keypad mode.
ESC]	OSC	(Should be: Operating system command) ESC] P nrrggbb: set palette, with parameter given in 7 hexadecimal digits after the final P :-(. Here n is the color (0–16), and rrrggbb indicates the red/green/blue values (0–255). ESC] R: reset palette.

ECMA-48 CSI SEQUENCES

CSI (or ESC [) is followed by a sequence of parameters, at most `NPAR(16)`, that are decimal numbers separated by semicolons. An empty or absent parameter is taken to be 0. The sequence of parameters may be preceded by a single question mark.

However, after CSI [(or ESC [) a single character is read and this entire sequence is ignored. (The idea is to ignore an echoed function key.)

The action of a CSI sequence is determined by its final character.

<i>Character</i>	<i>Function</i>	<i>Description</i>
@	ICH	Insert the indicated # of blank characters.
A	CUU	Move cursor up the indicated # of rows.
B	CUD	Move cursor down the indicated # of rows.
C	CUF	Move cursor right the indicated # of columns.
D	CUB	Move cursor left the indicated # of columns.
E	CNL	Move cursor down the indicated # of rows, to column 1.
F	CPL	Move cursor up the indicated # of rows, to column 1.
G	CHA	Move cursor to indicated column in current row.
H	CUP	Move cursor to the indicated row, column (origin at 1,1).
J	ED	Erase display (default: from cursor to end of display). ESC [1 J: erase from start to cursor. ESC [2 J: erase whole display.
K	EL	Erase line (default: from cursor to end of line). ESC [1 K: erase from start of line to cursor. ESC [2 K: erase whole line.
L	IL	Insert the indicated # of blank lines.
M	DL	Delete the indicated # of lines.
P	DCH	Delete the indicated # of characters on the current line.
X	ECH	Erase the indicated # of characters on the current line.
a	HPR	Move cursor right the indicated # of columns.
c	DA	Answer ESC [? 6 c: 'I am a VT102'.
d	VPA	Move cursor to the indicated row, current column.
e	VPR	Move cursor down the indicated # of rows.
f	HVP	Move cursor to the indicated row, column.

<i>Character</i>	<i>Function</i>	<i>Description</i>
g	TBC	Without parameter: clear tab stop at the current position. ESC [3 g: delete all tab stops.
h	SM	Set mode.
l	RM	Reset mode.
m	SGR	Set attributes.
n	DSR	Status report.
q	DECLL	Set keyboard LEDs. ESC [0 q: clear all LEDs ESC [1 q: set Scroll Lock LED ESC [2 q: set Num Lock LED ESC [3 q: set Caps Lock LED
r	DECSTBM	Set scrolling region; parameters are top and bottom row.
s	?	Save cursor location.
u	?	Restore cursor location.
'	HPA	Move cursor to indicated column in current row.

ECMA-48 SET GRAPHICS RENDITION

The ECMA-48 SGR sequence ESC [<parameters> m sets display attributes. Several attributes can be set in the same sequence.

<i>Parameter</i>	<i>Result</i>
0	Reset all attributes to their defaults.
1	Set bold.
2	Set half-bright (simulated with color on a color display).
4	Set underscore (simulated with color on a color display). (The colors used to simulate dim or underline are set using ESC])
5	Set blink.
7	Set reverse video.
10	Reset selected mapping, display control flag, and toggle meta flag.
11	Select null mapping, set display control flag, reset toggle meta flag.
12	Select null mapping, set display control flag, set toggle meta flag. (The toggle meta flag causes the high bit of a byte to be toggled before the mapping table translation is done.)
21	Set normal intensity. (This is not compatible with ECMA-48.)
22	Set normal intensity.
24	Underline off.
25	Blink off.
27	Reverse video off.
30	Set black foreground.
31	Set red foreground.
32	Set green foreground.
33	Set brown foreground.
34	Set blue foreground.
35	Set magenta foreground.

<i>Parameter</i>	<i>Result</i>
36	Set cyan foreground.
37	Set white foreground.
38	Set underscore on, set default foreground color.
39	Set underscore off, set default foreground color.
40	Set black background.
41	Set red background.
42	Set green background.
43	Set brown background.
44	Set blue background.
45	Set magenta background.
46	Set cyan background.
47	Set white background.
49	Set default background color.

ECMA-48 MODE SWITCHES

ESC [3 h	DECCRM (default off): Display control chars.
ESC [4 h	DECIM (default off): Set insert mode.
ESC [20 h	LF/NL (default off): Automatically follow echo of LF, VT, or FF with CR.

ECMA-48 STATUS REPORT COMMANDS

ESC [5 n	Device status report (DSR): Answer is ESC [0 n (Terminal OK).
ESC [6 n	Cursor position report (CPR): Answer is ESC [y ; x R, where x, y is the cursor location.

DEC PRIVATE MODE(DECSET/DECRST) SEQUENCES

These are not described in ECMA-48. The Set Mode sequences are listed; the Reset Mode sequences are obtained by replacing the final h by 1.

ESC [? 1 h	DECCKM (default off): When set, the cursor keys send an ESC 0 prefix, rather than ESC [.
ESC [? 3 h	DECCOLM (default off = 80 columns): 80/132 col mode switch. The driver sources note that this alone does not suffice; some user-mode utility such as <code>resizecons(8)</code> has to change the hardware registers on the console video card.
ESC [? 5 h	DECSNM (default off): Set reverse-video mode.
ESC [? 6 h	DECOM (default off): When set, cursor addressing is relative to the upper left corner of the scrolling region.
ESC [? 7 h	DECAWM (default on): Set autowrap on. In this mode, a graphics character emitted after column 80 (or column 132 of DECCOLM is on) forces a wrap to the beginning of the following line first.
ESC [? 8 h	DECARM (default on): Set keyboard autorepeat on.
ESC [? 9	h X10 Mouse Reporting (default off): Set reporting mode to 1 (or reset to 0). (See "Mouse Tracking.")
ESC [? 25 h	DECCM (default on): Make cursor visible.
ESC [? 1000 h	X11 Mouse Reporting (default off): Set reporting mode to 2 (or reset to 0). (See "Mouse Tracking.")

LINUX CONSOLE PRIVATE CSI SEQUENCES

The following sequences are neither ECMA-48 nor native VT102. They are native to the Linux console driver. Colors are in SGR parameters: 0 = black, 1 = red, 2 = green, 3 = brown, 4 = blue, 5 = magenta, 6 = cyan, 7 = white.

ESC [1 ; n]	Set color <i>n</i> as the underline color
ESC [2 ; n]	Set color <i>n</i> as the dim color
ESC [8]	Make the current color pair the default attributes
ESC [9 ; n]	Set screen blank time-out to <i>n</i> minutes
ESC [10 ; n]	Set bell frequency in Hz
ESC [11 ; n]	Set bell duration in msec
ESC [12 ; n]	Bring specified console to the front
ESC [13]	Unblank the screen
ESC [14]	Set the VESA powerdown interval

CHARACTER SETS

The kernel knows about four translations of bytes into console-screen symbols. The four tables are

- Latin1 to PC
- VT100 graphics to PC
- PC to PC
- User-defined

There are two character sets, called G0 and G1, and one of them is the current character set. (Initially G0.) Typing `^N` causes G1 to become current, `^O` causes G0 to become current.

These variables G0 and G1 point to a translation table, and can be changed by the user. Initially, they point at the first two tables, Latin1 to PC and VT100 graphics to PC, respectively. The sequences ESC (B and ESC (0 and ESC (U and ESC (K cause G0 to point at the first, second, third, and fourth translation tables in the preceding list, respectively. The sequences ESC) B and ESC) 0 and ESC) U and ESC) K cause G1 to point at the first, second, third, and fourth translation tables in the preceding list, respectively.

The sequence ESC c causes a terminal reset, which is what you want if the screen is all garbled. The oft-advised “`echo ^V^O`” will only make G0 current, but there is no guarantee that G0 points at the first table. In some distributions there is a program `reset(1)` that just does `echo ^[c`. If your `terminfo` entry for the console is correct (and has an entry `rs1=c`), then `tput reset` will also work.

The user-defined mapping table can be set using `mapscrn(8)`. The result of the mapping is that if a symbol *c* is printed, the symbol *s* = `map[c]` is sent to the video memory. The bitmap that corresponds to *s* is found in the character ROM, and can be changed using `setfont(8)`.

MOUSE TRACKING

The mouse tracking facility is intended to return `xterm`-compatible mouse status reports. Because the console driver has no way to know the device or type of the mouse, these reports are returned in the console input stream only when the virtual terminal driver receives a mouse update `ioctl`. These `ioctls` must be generated by a mouse-aware user-mode application such as the `gpm(8)` daemon.

Parameters for all mouse tracking escape sequences generated by `xterm` encode numeric parameters in a single character as `value+040`. For example, `1` is 1. The screen coordinate system is 1-based.

The `x10` compatibility mode sends an escape sequence on button press encoding the location and the mouse button pressed. It is enabled by sending ESC [? 9 h and disabled with ESC [? 9 l. On button press, `xterm` sends ESC [M bxy (six characters). Here *b* is button 1, and *x* and *y* are the *x* and *y* coordinates of the mouse when the button was pressed. This is the same code the kernel also produces.

Normal tracking mode (not implemented in Linux 2.0.24) sends an escape sequence on both button press and release. Modifier information is also sent. It is enabled by sending ESC [? 1000 h and disabled with ESC [1000 l. On button press or release, `xterm` sends ESC [M bxy. The low two bits of `b` encode button information: 0=MB1 pressed, 1=MB2 pressed, 2=MB3 pressed, 3=release. The upper bits encode what modifiers were down when the button was pressed and are added together: 4=Shift, 8=Meta, 16=Control. Again, `x` and `y` are the `x` and `y` coordinates of the mouse event. The upper-left corner is (1,1).

COMPARISONS WITH OTHER TERMINALS

Many different terminal types are described, like the Linux console, as being VT100-compatible. Here we discuss differences between the Linux console and the two most important others, the DEC VT102 and `xterm(1)`.

CONTROL-CHARACTER HANDLING

The `vt102` also recognized the following control characters:

NUL (0x00) was ignored.

ENQ (0x05) triggered an answerback message.

DC1 (0x11, ^Q, XON) resumed transmission.

DC3 (0x13, ^S, XOFF) caused `vt100` to ignore (and stop transmitting) all codes except XOFF and XON.

VT100-like DC1/DC3 processing may be enabled by the `tty` driver.

The `xterm` program (in `vt100` mode) recognizes the control characters BEL, BS, HT, LF, VT, FF, CR, SO, SI, ESC.

ESCAPE SEQUENCES

The following VT100 console sequences are not implemented on the Linux console:

<i>Escape Sequence</i>	<i>Function</i>	<i>Description</i>
ESC N	SS2	Single shift 2. (Select G2 character set for the next character only.)
ESC O	SS3	Single shift 3. (Select G3 character set for the next character only.)
ESC P	DCS	Device control string (ended by ESC \).
ESC X	SOS	Start of string.
ESC ^	PM	Privacy message (ended by ESC \).
ESC \	ST	String terminator.
ESC * ...		Designate G2 character set.
ESC + ...		Designate G3 character set.

The program `xterm` (in `vt100` mode) recognizes ESC c, ESC # 8, ESC >, ESC =, ESC D, ESC E, ESC H, ESC M, ESC N, ESC O, ESC P ... ESC ESC Z (it answers ESC [? 1 ; 2 c, "I am a vt100 with advanced video option") and ESC ^ ... ESC with the same meanings as indicated above. It accepts ESC (, ESC), ESC *, ESC + followed by 0, A, B for the DEC special character and line drawing set, UK, and USASCII, respectively. It accepts ESC] for the setting of certain resources:

```
ESC ] 0 ; txt BEL      Set icon name and window title to txt.
ESC ] 1 ; txt BEL      Set icon name to txt.
ESC ] 2 ; txt BEL      Set window title to txt.
ESC ] 4 6 ; name BEL   Change log file to name (normally disabled by a compile-time option).
ESC ] 5 0 ; fn BEL     Set font to fn.
```

It recognizes the following with slightly modified meaning:

```
ESC 7 DECSC           Save cursor
ESC 8 DECRC           Restore cursor
```

It also recognizes

ESC F		Cursor to lower-left corner of screen (if enabled by the <code>hpLowerLeftBugCompat</code> resource).
ESC l		Memory lock (per HP terminals). Locks memory above the cursor.
ESC m		Memory unlock (per HP terminals).
ESC n	LS2	Invoke the G2 character set.
ESC o	LS3	Invoke the G3 character set.
ESC j	LS3R	Invoke the G3 character set as GR.
		Has no visible effect in <code>xterm</code> .
ESC g	LS2R	Invoke the G2 character set as GR.
		Has no visible effect in <code>xterm</code> .
ESC `	LS1R	Invoke the G1 character set as GR.
		Has no visible effect in <code>xterm</code> .

It does not recognize ESC % ...

CSI SEQUENCES

The `xterm` program (as of `XFree86 3.1.2G`) does not recognize the blink or invisible-mode SGRs. Stock X11R6 versions do not recognize the color-setting SGRs. All other ECMA-48 CSI sequences recognized by Linux are also recognized by `xterm`, and vice versa.

The `xterm` program will recognize all of the DEC Private Mode sequences listed earlier, but none of the Linux private-mode sequences. For discussion of `xterm`'s own private-mode sequences, refer to the *Xterm Control Sequences* document by Edward Moy and Stephen Gildea, available with the `x` distribution.

BUGS

In 2.0.23, CSI is broken, and NUL is not ignored inside escape sequences.

console ioctl

`console ioctl`—Ioctls for console terminal and virtual consoles

DESCRIPTION

The following Linux-peculiar `ioctl` requests are supported. Each requires a third argument, assumed here to be `argp`.

WARNING

If you use the following information, you are going to burn yourself. Ioctls are undocumented Linux internals, liable to be changed without warning. Use POSIX functions.

KDGETLED	Get state of LEDs. <i>argp</i> points to a long <i>int</i> . The lower three bits of <i>*argp</i> are set to the state of the LEDs, as follows:									
	<table> <tbody> <tr> <td>LED_CAP</td> <td>0x04</td> <td>caps lock LED</td> </tr> <tr> <td>LED_NUM</td> <td>0x02</td> <td>num lock LED</td> </tr> <tr> <td>LED_SCR</td> <td>0x01</td> <td>scroll lock LED</td> </tr> </tbody> </table>	LED_CAP	0x04	caps lock LED	LED_NUM	0x02	num lock LED	LED_SCR	0x01	scroll lock LED
LED_CAP	0x04	caps lock LED								
LED_NUM	0x02	num lock LED								
LED_SCR	0x01	scroll lock LED								
KDSETLED	Set the LEDs. The LEDs are set to correspond to the lower three bits of <i>argp</i> . However, if a higher order bit is set, the LEDs revert to normal, displaying the state of the keyboard functions of caps lock, num lock, and scroll lock. Before 1.1.54, the LEDs just reflected the state of the corresponding keyboard flags, and <i>KDGETLED</i> / <i>KDSETLED</i> would also change the keyboard flags. Since 1.1.54 the LEDs can be made to display arbitrary information, but by default they display the keyboard flags. The following two ioctls are used to access the keyboard flags.									
KDGKBLD	Get keyboard flags <i>CapsLock</i> , <i>NumLock</i> , <i>ScrollLock</i> (not lights). <i>argp</i> points to a char that is set to the flag state. The low order three bits (mask 0x7) get the current flag state, and the low order bits of the next nibble (mask 0x70) get the default flag state (since 1.1.54).									
KDSKBLD	Set keyboard flags <i>CapsLock</i> , <i>NumLock</i> , <i>ScrollLock</i> (not lights). <i>argp</i> has the desired flag state. The low order three bits (mask 0x7) have the flag state, and the low order bits of the next nibble (mask 0x70) have the default flag state (since 1.1.54).									
KDGKBTYPE	Get keyboard type. This returns the value <i>KB_101</i> , defined as 0x02.									
KDADDIO	Add I/O port as valid. Equivalent to <i>ioperm</i> (<i>arg</i> , 1, 1).									
KDDELIO	Delete I/O port as valid. Equivalent to <i>ioperm</i> (<i>arg</i> , 1, 0).									
KDENABIO	Enable I/O to video board. Equivalent to <i>ioperm</i> (0x3b4, 0x3df-0x3b4+1, 1).									
KDDISABIO	Disable I/O to video board. Equivalent to <i>ioperm</i> (0x3b4, 0x3df-0x3b4+1, 0).									
KDSETMODE	Set text/graphics mode. <i>argp</i> is one of these:									
	<table> <tbody> <tr> <td>KD_TEXT</td> <td>0x00</td> </tr> <tr> <td>KD_GRAPHICS</td> <td>0x01</td> </tr> </tbody> </table>	KD_TEXT	0x00	KD_GRAPHICS	0x01					
KD_TEXT	0x00									
KD_GRAPHICS	0x01									
KDGETMODE	Get text/graphics mode. <i>argp</i> points to a long which is set to one of the above values.									
KDMKTONE	Generate tone of specified length. The lower 16 bits of <i>argp</i> specify the period in clock cycles, and the upper 16 bits give the duration in msec. If the duration is zero, the sound is turned off. Control returns immediately. For example, <i>argp</i> = (125<<16) + 0x637 would specify the beep normally associated with a <i>ctrl-G</i> .									
KIOCSOUND	Start or stop sound generation. The lower 16 bits of <i>argp</i> specify the period in clock cycles (that is, <i>argp</i> = 1193180/frequency). <i>argp</i> = 0 turns sound off. In either case, control returns immediately.									
GIO_CMAP	Get the current default color map from kernel. <i>argp</i> points to a 48-byte array. (Since 1.3.3.)									
PIO_CMAP	Change the default text-mode color map. <i>argp</i> points to a 48-byte array that contains, in order, the red, green, and blue values for the 16 available screen colors: 0 is off, and 255 is full intensity. The default colors are, in order: black, dark red, dark green, brown, dark blue, dark purple, dark cyan, light grey, dark grey, bright red, bright green, yellow, bright blue, bright purple, bright cyan, and white. (Since 1.3.3.)									
GIO_FONT	Gets 256-character screen font in expanded form. <i>argp</i> points to an 8192-byte array. Fails with error code <i>EINVAL</i> if the currently loaded font is a 512-character font, or if the console is not in text mode.									

GIO_FONTX	Gets screen font and associated information. <code>argp</code> points to a <code>struct consolefontdesc</code> (see <code>PIO_FONTX</code>). On call, the <code>charcount</code> field should be set to the maximum number of characters that would fit in the buffer pointed to by <code>chardata</code> . On return, the <code>charcount</code> and <code>charheight</code> are filled with the respective data for the currently loaded font, and the <code>chardata</code> array contains the font data if the initial value of <code>charcount</code> indicated enough space was available; otherwise the buffer is untouched and <code>errno</code> is set to <code>ENOMEM</code> . (Since 1.3.1.)
PIO_FONT	Sets 256-character screen font. Load font into the EGA/VGA character generator. <code>argp</code> points to a 8192-byte map, with 32 bytes per character. Only first <code>N</code> of them are used for an <code>8xN</code> font ($0 < N \leq 32$). This call also invalidates the Unicode mapping.
PIO_FONTX	Sets screen font and associated rendering information. <code>argp</code> points to a <pre> struct consolefontdesc { u_short charcount; /* characters in font (256 or 512) */ u_short charheight; /* scan lines per character (1-32) */ char *chardata; /* font data in expanded form */ }; </pre>
PIO_FONTRESET	If necessary, the screen will be appropriately resized, and <code>SIGWINCH</code> sent to the appropriate processes. This call also invalidates the Unicode mapping. (Since 1.3.1.) Resets the screen font, size, and Unicode mapping to the bootup defaults. <code>argp</code> is unused, but should be set to <code>NULL</code> to ensure compatibility with future versions of Linux. (Since 1.3.28.)
GIO_SCRNMAP	Get screen mapping from kernel. <code>argp</code> points to an area of size <code>E_TABSZ</code> , which is loaded with the font positions used to display each character. This call is likely to return useless information if the currently loaded font is more than 256 characters.
GIO_UNISCRNMAP	Get full Unicode screen mapping from kernel. <code>argp</code> points to an area of size <code>E_TABSZ*sizeof(unsigned short)</code> , which is loaded with the Unicodes each character represent. A special set of Unicodes, starting at <code>U+F000</code> , are used to represent “direct to font” mappings. (Since 1.3.1.)
PIO_SCRNMAP	Loads the user-definable (fourth) table in the kernel that maps bytes into console screen symbols. <code>argp</code> points to an area of size <code>E_TABSZ</code> .
PIO_UNISCRNMAP	Loads the user-definable (fourth) table in the kernel that maps bytes into Unicodes, which are then translated into screen symbols according to the currently loaded Unicode-to-font map. Special Unicodes starting at <code>U+F000</code> can be used to map directly to the font symbols. (Since 1.3.1.)
GIO_UNIMAP	Get Unicode-to-font mapping from kernel. <code>argp</code> points to a <pre> struct unimapdesc { u_short entry_ct; struct unipair *entries; }; </pre> where <code>entries</code> points to an array of <pre> struct unipair { u_short unicode; u_short fontpos; }; </pre> (Since 1.1.92.)
PIO_UNIMAP	Put Unicode-to-font mapping in kernel. <code>argp</code> points to a <code>struct unimapdesc</code> . (Since 1.1.92.)

PIO_UNIMAPCLR	<p>Clear table, possibly advise hash algorithm. <code>argp</code> points to a</p> <pre>struct unimapinit { u short advised hashsize; /* 0 if no opinion */ u short advised hashstep; /* 0 if no opinion */ u short advised hashlevel; /* 0 if no opinion */ };</pre> <p>(Since 1.1.92.)</p>
KDGKBMODE	<p>Gets current keyboard mode. <code>argp</code> points to a long, which is set to one of these:</p> <pre>K_RAW 0x00 K_XLATE 0x01 K_MEDIUMRAW 0x02 K_UNICODE 0x03</pre>
KDSKBMODE	<p>Sets current keyboard mode. <code>argp</code> is a long equal to one of the above values.</p>
KDGKBMETA	<p>Gets meta key handling mode. <code>argp</code> points to a long which is set to one of these:</p> <pre>K_METABIT 0x03 Set high order bit K_ESCPREFIX 0x04 Escape prefix</pre>
KDSKBMETA	<p>Sets meta key handling mode. <code>argp</code> is a long equal to one of the preceding values.</p>
KDGKBENT	<p>Gets one entry in key translation table (keycode to action code). <code>argp</code> points to a</p> <pre>struct kbentry { u_char kb_table; u_char kb_index; u_short kb_value; };</pre> <p>with the first two members filled in: <code>kb_table</code> selects the key table ($0 \leq kb_table < MAX_NR_KEYMAPS$), and <code>kb_index</code> is the keycode ($0 \leq kb_index < NR_KEYS$). <code>kb_value</code> is set to the corresponding action code, or <code>K_HOLE</code> if there is no such key, or <code>K_NOSUCHMAP</code> if <code>kb_table</code> is invalid.</p>
KDSKBENT	<p>Sets one entry in translation table. <code>argp</code> points to a struct <code>kbentry</code>.</p>
KDGKBSENT	<p>Gets one function key string. <code>argp</code> points to a</p> <pre>struct kbsentry { u_char kb_func; u_char kb_string[512]; };</pre> <p><code>kb_string</code> is set to the (NULL-terminated) string corresponding to the <code>kb_func</code> function key action code.</p>
KDSKBSENT	<p>Sets one function key string entry. <code>argp</code> points to a struct <code>kbsentry</code>.</p>
KDGKBDIACR	<p>Read kernel accent table. <code>argp</code> points to a</p> <pre>struct kbdiacrs { unsigned int kb_cnt; struct kbdiacr kbdiacr[256]; };</pre> <p>where <code>kb_cnt</code> is the number of entries in the array, each of which is a struct <code>kbdiacr</code> { <code>u_char diacr, base, result</code> };</p>
KDGETKEYCODE	<p>Read kernel keycode table entry (scan code to keycode). <code>argp</code> points to a struct <code>kbkeycode</code> { <code>unsigned int scancode, keycode</code> };</p> <p><code>keycode</code> is set to correspond to the given <code>scancode</code>. ($89 \leq scancode \leq 255$ only. For $1 \leq scancode \leq 88$, <code>keycode==scancode</code>.) (Since 1.1.63.)</p>
KDSETKEYCODE	<p>Write kernel keycode table entry. <code>argp</code> points to struct <code>kbkeycode</code>. (Since 1.1.63.)</p>

KDSIGACCEPT	The calling process indicates its willingness to accept the signal <code>argp</code> when it is generated by pressing an appropriate key combination. (1 <= <code>argp</code> <=NSIG). (See <code>spawn_console()</code> in <code>linux/drivers/char/keyboard.c</code> .)						
VT_OPENQRY	Returns the first available (nonopened) console. <code>argp</code> points to an int that is set to the number of the vt (1 <= * <code>argp</code> <=MAX_NR_CONSOLES).						
VT_GETMODE	Get mode of active vt. <code>argp</code> points to a <pre>struct vt_mode { char mode; /*vtmode*/ char waitv; /* if set, hang on writes if not active */ short relsig; /* signal to raise on release req */ short acqsig; /* signal to raise on acquisition */ short frsig; /* unused (set to 0) */ };</pre> <p>mode is set to one of these values:</p> <table> <tbody> <tr> <td>VT_AUTO</td> <td>Auto vt switching</td> </tr> <tr> <td>VT_PROCESS</td> <td>Process controls switching</td> </tr> <tr> <td>VT_ACKACQ</td> <td>Acknowledge switch</td> </tr> </tbody> </table>	VT_AUTO	Auto vt switching	VT_PROCESS	Process controls switching	VT_ACKACQ	Acknowledge switch
VT_AUTO	Auto vt switching						
VT_PROCESS	Process controls switching						
VT_ACKACQ	Acknowledge switch						
VT_SETMODE	Set mode of active vt. <code>argp</code> points to a struct <code>vt_mode</code> .						
VT_GETSTATE	Get global vt state info. <code>argp</code> points to a <pre>struct vt_stat { ushort v_active; /* active vt */ ushort v_signal; /*signalto send*/ ushort v_state; /*vtbitmask*/ };</pre> <p>For each vt in use, the corresponding bit in the <code>v</code> state member is set. (Kernels 1.0 through 1.1.92.)</p>						
VT_RELDISP	Release a display.						
VT_ACTIVATE	Switch to vt <code>argp</code> (1 <= <code>argp</code> <=MAX_NR_CONSOLES).						
VT_WAITACTIVE	Wait until vt <code>argp</code> has been activated.						
VT_DISALLOCATE	Deallocate the memory associated with vt <code>argp</code> . (Since 1.1.54.)						
VT_RESIZE	Set the kernel's idea of screensize. <code>argp</code> points to a <pre>struct vt_sizes { ushort v_rows; /*#rows*/ ushort v_cols; /*#columns */ ushort v_scrollsize; /* no longer used */ };</pre> <p>Note that this does not change the video mode. See <code>resizecons(8)</code>. (Since 1.1.54.)</p>						
VT_RESIZEX	Set the kernel's idea of various screen parameters. <code>argp</code> points to a <pre>struct vt_consize { ushort v_rows; /* number of rows */ ushort v_cols; /* number of columns */ ushort v_vlin; /* number of pixel rows on screen */ ushort v_clin; /* number of pixel rows per character */ ushort v_vcol; /* number of pixel columns on screen */ ushort v_ccol; /* number of pixel columns per character */ };</pre> <p>Any parameter may be set to zero, indicating no change, but if multiple parameters are set, they must be self-consistent. Note that this does not change the video mode. See <code>resizecons(8)</code>. (Since 1.3.3.)</p>						

The action of the following ioctls depends on the first byte in the `struct` pointed to by `argp`, referred to here as the `subcode`. These are legal only for the superuser or the owner of the current `tty`.

TIOCLINUX, subcode=0	Dump the screen. Disappeared in 1.1.92. (With kernel 1.1.92 or later, read from <code>/dev/vcsN</code> or <code>/dev/vcsaN</code> instead.)
TIOCLINUX, subcode=1	Get task information. Disappeared in 1.1.92.
TIOCLINUX, subcode=2	Set selection. <code>argp</code> points to a <code>struct{fchar subcode; short xs, ys, xe, ye; short sel_mode; }</code> <code>xs</code> and <code>ys</code> are the starting column and row. <code>xe</code> and <code>ye</code> are the ending column and row. (Upper-left corner is <code>row=column=1</code> .) <code>sel_mode</code> is 0 for character-by-character selection, 1 for word-by-word selection, or 2 for line-by-line selection. The indicated screen characters are highlighted and saved in the static array <code>sel</code> buffer in <code>devices/char/console.c</code> .
TIOCLINUX, subcode=3	Paste selection. The characters in the selection buffer are written to <code>fd</code> .
TIOCLINUX, subcode=4	Unblank the screen.
TIOCLINUX, subcode=5	Sets contents of a 256-bit look up table defining characters in a “word”, for word-by-word selection. (Since 1.1.32.)
TIOCLINUX, subcode=6	<code>argp</code> points to a <code>char</code> that is set to the value of the kernel variable <code>shift state</code> . (Since 1.1.32.)
TIOCLINUX, subcode=7	<code>argp</code> points to a <code>char</code> that is set to the value of the kernel variable <code>report mouse</code> . (Since 1.1.33.)
TIOCLINUX, subcode=8	Dump screen width and height, cursor position, and all the character-attribute pairs. (Kernels 1.1.67 through 1.1.91 only. With kernel 1.1.92 or later, read from <code>/dev/vcsa*</code> instead.)
TIOCLINUX, subcode=9	Restore screen width and height, cursor position, and all the character-attribute pairs. (Kernels 1.1.67 through 1.1.91 only. With kernel 1.1.92 or later, write to <code>/dev/vcsa*</code> instead.)
TIOCLINUX, subcode=10	Handles the power saving feature of the new generation of monitors. VESA screen blanking mode is set to <code>argp[1]</code> , which governs what screen blanking does: <ul style="list-style-type: none"> 0 Screen blanking is disabled. 1 The current video adapter register settings are saved, then the controller is programmed to turn off the vertical synchronization pulses. This puts the monitor into standby mode. If your monitor has an <code>Off_Mode</code> timer, then it will eventually power down by itself. 2 The current settings are saved, then both the vertical and horizontal synchronization pulses are turned off. This puts the monitor into off mode. If your monitor has no <code>Off_Mode</code> timer, or if you want your monitor to power down immediately when the blank timer times out, then you choose this option. (Caution: Powering down frequently will damage the monitor.) (Since 1.1.76.)

RETURN VALUES

-1 for error, and `errno` is set.

ERRORS

`errno` may take on these values:

EBADF	File descriptor is invalid.
ENOTTY	File descriptor is not associated with a character special device, or the specified request does not apply to it.

EINVAL	File descriptor or <code>argp</code> is invalid.
EPERM	Permission violation.

WARNING

Do not regard this man page as documentation of the Linux console ioctls. This is provided for the curious only, as an alternative to reading the source. Ioctls are undocumented Linux internals, liable to be changed without warning. (And indeed, this page more or less describes the situation as of kernel version 1.1.94; there are many minor and not-so-minor differences with earlier versions.)

Very often, ioctls are introduced for communication between the kernel and one particular well-known program (`fdisk`, `hdparm`, `setserial`, `tunelp`, `loadkeys`, `selection`, `setfont`, and so on), and their behavior will be changed when required by this particular program.

Programs using these ioctls will not be portable to other versions of UNIX, will not work on older versions of Linux, and will not work on future versions of Linux.

Use POSIX functions.

fd

`fd`—Floppy disk device

CONFIGURATION

Floppy drives are block devices with major number 2. Typically, they are owned by `root.floppy` (that is, user `root`, group `floppy`) and have either mode `0660` (access checking via group membership) or mode `0666` (everybody has access). The minor numbers encode the device type, drive number, and controller number. For each device type (that is, combination of density and track count), there is a base minor number. To this base number, add the drive's number on its controller and 128 if the drive is on the secondary controller. In the following device tables, `n` represents the drive number.

WARNING

If you use formats with more tracks than supported by your drive, you may cause it mechanical damage. Trying once if more tracks than the usual 40/80 are supported should not damage it, but no warranty is given for that. Don't create device entries for those formats to prevent their usage if you are not sure.

Drive-independent device files that automatically detect the media format and capacity are

DESCRIPTION

`fd` special files access the floppy disk drives in raw mode. The following `ioctl(2)` calls are supported by `fd` devices:

`FDCLRPRM` clears the media information of a drive (geometry of disk in drive).

`FDSETPRM` sets the media information of a drive. The media information will be lost when the media is changed.

`FDDEFPRM` sets the media information of a drive (geometry of disk in drive). The media information will not be lost when the media is changed. This will disable autodetection. In order to re-enable autodetection, you have to issue an `FDCLRPRM`.

`FDGETDRVTYPE` displays the type of a drive (name parameter). For formats that work in several drive types, `FDGETDRVTYPE` returns a name that is appropriate for the oldest drive type that supports this format.

`FDLUSH` invalidates the buffer cache for the given drive.

`FDLUSH` invalidates the buffer cache for the given drive.

`FDSETPMAXERRS` sets the error thresholds for reporting errors, aborting the operation, recalibrating, resetting, and reading sector by sector.

`FDSETPMAXERRS` gets the current error thresholds.

`FDGETDRVTYPE` gets the internal name of the drive.

`FDWERRORCLR` clears the write error statistics.

`FDWERRORGET` reads the write error statistics. These include the total number of write errors, the location and disk of the first write error, and the location and disk of the last write error. Disks are identified by a generation number that is incremented at (almost) each disk change.

`FDTWADDLE` switches the drive motor off for a few microseconds. This might be needed in order to access a disk whose sectors are too close together.

`FDSETDRVPRM` sets various drive parameters.

`FDGETDRVPRM` reads these parameters back.

`FDGETDRVSTAT` gets the cached drive state (disk changed, write protected et al.)

`FDPOLLDVSTAT` polls the drive and return its state.

`FDGETFDCSTAT` gets the floppy controller state.

`FDRESET` resets the floppy controller under certain conditions.

`FDRAWCMD` sends a raw command to the floppy controller.

For more precise information, consult also the `<linux/fd.h>` and `<linux/fdreg.h>` include files, as well as the manual page for floppy control.

NOTES

The various formats allow you to read and write many types of disks. However, if a floppy is formatted with a too small intersector gap, performance may drop, up to needing a few seconds to access an entire track. To prevent this, use interleaved formats. It is not possible to read floppies that are formatted using GCR (group code recording), which is used by Apple II and Macintosh computers (800K disks). Reading floppies that are hard sectored (one hole per sector, with the index hole being a little skewed) is not supported. This used to be common with older 8-inch floppies.

hd

hd—MFM/IDE hard disk device

DESCRIPTION

`hd*` are block devices to access MFM/IDE hard disk drives in raw mode. The master drive on the primary IDE controller (major device number 3) is `hda`; the slave drive is `hdb`. The master drive of the second controller (major device number 22) is `hdc` and the slave `hdd`.

General IDE block device names have the form `hdX`, or `hdXP`, where `X` is a letter denoting the physical drive, and `P` is a number denoting the partition on that physical drive. The first form, `hdX`, is used to address the whole drive. Partition numbers are assigned in the order the partitions are discovered, and only nonempty, nonextended partitions get a number. However, partition numbers 1–4 are given to the four partitions described in the MBR (the primary partitions), regardless of whether they are unused or extended. Thus, the first logical partition will be `hdX5`. Both DOS-type partitioning and BSD-disk label partitioning are supported. You can have at most 63 partitions on an IDE disk.

For example, `/dev/hda` refers to all of the first IDE drive in the system; and `/dev/hdb3` refers to the third DOS primary partition on the second one.

They are typically created by the following:

```
mknod -m 660 /dev/hda b 3 0
mknod -m 660 /dev/hda1 b 3 1
mknod -m 660 /dev/hda2 b 3 2
...
mknod -m 660 /dev/hda8 b 3 8
mknod -m 660 /dev/hdb b 3 64
mknod -m 660 /dev/hdb1 b 3 65
mknod -m 660 /dev/hdb2 b 3 66
...
mknod -m 660 /dev/hdb8 b 3 72
chown root.disk /dev/hd*
```

ispell

ispell—Format of `ispell` dictionaries and `affix` files

DESCRIPTION

`ispell(1)` requires two files to define the language that it is spell checking. The first file is a dictionary containing words for the language, and the second is an `affix` file that defines the meaning of special flags in the dictionary. The two files are combined by `buildhash` (see `spell(1)`) and written to a hash file that is not described here.

A raw `ispell` dictionary (either the main dictionary or your own personal dictionary) contains a list of words, one per line. Each word may optionally be followed by a slash (/) and one or more flags, which modify the root word as explained later. Depending on the options with which `ispell` was built, case may or may not be significant in either the root word or the flags, independently. Specifically, if the compile-time option `CAPITALIZATION` is defined, case is significant in the root word; if not, case is ignored in the root word. If the compile-time option `MASKBITS` is set to a value of 32, case is ignored in the flags; otherwise, case is significant in the flags. Contact your system administrator or `ispell` maintainer for more information (or use the `-vv` flag to find out). The dictionary should be sorted with the `-f` flag of `sort(1)` before the hash file is built; this is done automatically by `unchlist(1)`, which is the normal way of building dictionaries.

If the dictionary contains words that have string characters (see the `affix` file documentation, following), they must be written in the format given by the `defstringtype` statement in the `affix` file. This will be the case for most non-English languages. Be careful to use this format, rather than that of your favorite formatter, when adding words to a dictionary. If you add words to your personal dictionary during an `ispell` session, they will automatically be converted to the correct format. This feature can be used to convert an entire dictionary if necessary:

```
echo qqqqq > dummy.dict
buildhash dummy.dict affix-file dummy.hash
awk 'fprint "*"gENDfprint "#g' old-dict-file \
| ispell -a -T old-dict-string-type \
-d ./dummy.hash -p ./new-dict-file \
> /dev/null
rm dummy.*
```

The case of the root word controls the case of words accepted by `ispell`, as follows:

1. If the root word appears only in lowercase (for example, bob), it will be accepted in lowercase, capitalized, or all capitals.
2. If the root word appears capitalized (for example, Robert), it will not be accepted in all lowercase, but will be accepted capitalized or all in capitals.
3. If the root word appears all in capitals (for example, UNIX), it will only be accepted all in capitals.
4. If the root word appears with a “funny” capitalization (for example, ITCorp), a word will be accepted only if it follows that capitalization, or if it appears all in capitals.
5. More than one capitalization of a root word may appear in the dictionary. Flags from different capitalizations are combined using `OR`.

Redundant capitalizations (for example, bob and Bob) will be combined by `buildhash` and by `ispell` (for personal dictionaries), and can be removed from a raw dictionary by `munchlist`.

For example, the dictionary

```
bob
Robert
UNIX
ITCorp
ITCorp
```

will accept bob, Bob, BOB, Robert, ROBERT, UNIX, ITCorp, ITCorp, and ITCORP, and will reject all others. Some of the unacceptable forms are bOb, robert, Unix, and ItCorp.

As mentioned, root words in any dictionary may be extended by flags. Each flag is a single alphabetic character, which represents a prefix or suffix that may be added to the root to form a new word. For example, in an English dictionary the `o` flag can be added to `bathe` to make `bathed`. Because flags are represented as a single bit in the hashed dictionary, this results in significant space savings. The `munchlist` script will reduce an existing raw dictionary by adding flags when possible.

When a word is extended with an affix, the affix will be accepted only if it appears in the same case as the initial (prefix) or final (suffix) letter of the word. Thus, for example, the entry `UNIX/M` in the main dictionary (`M` means add an apostrophe and an `s` to make a possessive) would accept `UNIX'S` but would reject `UNIX's`. If `UNIX's` is legal, it must appear as a separate dictionary entry, and it will not be combined by `munchlist`. (In general, you don't need to worry about these things; `munchlist` guarantees that its output dictionary will accept the same set of words as its input, so all you have to do is add words to the dictionary and occasionally run `munchlist` to reduce its size.)

As mentioned, the affix definition file describes the affixes associated with particular flags. It also describes the character set used by the language.

Although the affix-definition grammar is designed for a line-oriented layout, it is actually a free-format grammar and can be laid out weirdly if you want. Comments are started by a pound (sharp) sign (`#`), and continue to the end of the line. Backslashes are supported in the usual fashion (`\nnn`, plus specials `\n`, `\r`, `\t`, `\v`, `\f`, `\b`, and the new hex format `\xnn`). Any character with special meaning to the parser can be changed to an uninterpreted token by backslashing it; for example, you can declare a flag named `asterisk` or `colon` with flag `n*:` or flag `n::`.

The grammar will be presented in a top-down fashion, with discussion of each element. An affix-definition file must contain exactly one table:

```
table :[headers][prefixes][suffixes]
```

At least one of prefixes and suffixes is required. They can appear in either order.

```
headers :[options ] char-sets
```

The headers describe options global to this dictionary and language. These include the character sets to be used and the formatter, and the defaults for certain *ispell* flags.

```
options : { fmtr-stmt | opt-stmt | flag-stmt | num-stmt }
```

The options statements define the defaults for certain *ispell* flags and for the character sets used by the formatters.

```
fmtr-stmt : { nroff-stmt | tex-stmt }
```

A `fmtr-stmt` statement describes characters that have special meaning to a formatter. Normally, this statement is not necessary, but some languages may have preempted the usual defaults for use as language-specific characters. In this case, these statements may be used to redefine the special characters expected by the formatter.

```
nroff-stmt : { nroffchars | troffchars } string
```

The `nroffchars` statement allows redefinition of certain `nroff` control characters. The string given must be exactly five characters long, and must list substitutions for the left and right parentheses, the period, the backslash, and the asterisk. (The right parenthesis is not currently used, but is included for completeness.) For example, the statement:

```
nroffchars { }.\ \*
```

would replace the left and right parentheses with left and right curly braces for purposes of parsing `nroff/troff` strings, with no effect on the others (admittedly a contrived example). Note that the backslash is escaped with a backslash.

```
tex-stmt : { TeXchars | texchars } string
```

The `TeXchars` statement allows redefinition of certain `TeX/LaTeX` control characters. The string given must be exactly thirteen characters long, and must list substitutions for the left and right parentheses, the left and right square brackets, the left and right curly braces, the left and right angle brackets, the backslash, the dollar sign, the asterisk, the period or dot, and the percent sign. For example, the statement:

```
texchars ( )\ [ ]< > \> < \> \$* . %
```

would replace the functions of the left and right curly braces with the left and right angle brackets for purposes of parsing TeX/LaTeX constructs, while retaining their functions for the `tib` bibliographic preprocessor. Note that the backslash, the left square bracket, and the right angle bracket must be escaped with a backslash.

```
opt-stmt : { cmpnd-stmt | aff-stmt }
cmpnd-stmt : compoundwords compound-opt
aff-stmt : allaffixes on-or-off
on-or-off : { on | off }
compound-opt : { on-or-off | controlled character }
```

An `opt-stmt`, used in the preceding code, controls certain `ispell` defaults that are best made language-specific. The `allaffixes` statement controls the default for the `-P` and `-m` options to `ispell`. If `allaffixes` is turned off (the default), `ispell` will default to the behavior of the `-P` flag: root/affix suggestions will only be made if there are no “near misses.” If `allaffixes` is turned on, `ispell` will default to the behavior of the `-m` flag: root/affix suggestions will always be made.

The `compoundwords` statement controls the default for the `-B` and `-C` options to `ispell`. If `compoundwords` is turned off (the default), `ispell` will default to the behavior of the `-B` flag: run-together words will be reported as errors. If `compoundwords` is turned on, `ispell` will default to the behavior of the `-C` flag: run-together words will be considered as compounds if both are in the dictionary. This is useful for languages such as German and Norwegian, which form large numbers of compound words. Finally, if `compoundwords` is set to `controlled`, only words marked with the flag indicated by character (which should not be otherwise used) will be allowed to participate in compound formation. Because this option requires the flags to be specified in the dictionary, it is not available from the command line.

```
flag-stmt : flagmarker character
```

The `flagmarker` statement describes the character that is used to separate affix flags from the root word in a raw dictionary file. This must be a character that is not found in any word (including in string characters; see following). The default is `/` because this character is not normally used to represent special characters in any language.

```
num-stmt : compoundmin digit
```

The `compoundmin` statement controls the length of the two components of a compound word. This only has an effect if `compoundwords` is turned on or if the `-C` flag is given to `ispell`. In that case, only words at least as long as the given minimum will be accepted as components of a compound. The default is 3 characters.

```
char-sets : norm-sets [ alt-sets ]
```

The character-set section describes the characters that can be part of a word, and defines their collating order. There must always be a definition of “normal” character sets; in addition, there may be one or more partial definitions of “alternate” sets that are used with various text formatters.

```
norm-sets :[deftype ] charset-group
```

A “normal” character set may optionally begin with a definition of the file suffixes that make use of this set. Following this are one or more character-set declarations.

```
deftype : defstringtype name deformatter suffix*
```

The *defstringtype* declaration gives a list of file suffixes that should make use of the default string characters defined as part of the base character set; it is only necessary if string characters are being defined. The `name` parameter is a string giving the unique name associated with these suffixes; often it is a formatter name. If the formatter is a member of the `troff` family, `nroff` should be used for the name associated with the most popular macro package; members of the TeX family should use `tex`. Other names may be chosen freely, but they should be kept simple, as they are used in `ispell`'s `-T` switch to specify a formatter type. The `deformatter` parameter specifies the deformatting style to use when processing files with the given suffixes. Currently, this must be either `tex` or `nroff`. The suffix parameters are a whitespace-separated list of strings which, if present at the end of a filename, indicate that the associated set of string characters should be used by default for this file. For example, the suffix list for the `troff` family typically includes suffixes such as `.ms`, `.me`, `.mm`, and so on.

```
charset-group : { char-stmt | string-stmt | dup-stmt}*
```

A `char-stmt` describes single characters; a `string-stmt` describes characters that must appear together as a string, and which usually represent a single character in the target language. Either may also describe conversion between uppercase and lowercase. A `dup-stmt` is used to describe alternate forms of string characters, so that a single dictionary may be used with several formatting programs that use different conventions for representing non-ASCII characters.

```
char-stmt : wordchars character-range
          | wordchars lowercase-range uppercase-range
          | boundarychars character-range
          | boundarychars lowercase-range uppercase-range
string-stmt : stringchar string
           | stringchar lowercase-string uppercase-string
```

Characters described with the `boundarychars` statement are considered part of a word only if they appear singly, embedded between characters declared with the `wordchars` or `stringchar` statements. For example, if the hyphen is a boundary character (useful in French), the string `foo-bar` would be a single word, but `-foo` would be the same as `foo`, and `foo-bar` would be two words separated by nonword characters.

If two ranges or strings are given in a `char-stmt` or `string-stmt`, the first describes characters that are interpreted as lowercase and the second describes uppercase. In the case of a `stringchar` statement, the two strings must be of the same length. Also, in a `stringchar` statement, the actual strings may contain both uppercase and characters themselves without difficulty; for instance, the statement:

```
stringchar "\\*(sS" "\\*(Ss"
```

is legal and will not interfere with (or be interfered with by) other declarations of "s" and "S" as lowercase and uppercase, respectively.

A final note on string characters: some languages collate certain special characters as if they were strings. For example, the German "a-umlaut" is traditionally sorted as if it were *ae*. `ispell` is not capable of this; each character must be treated as an individual entity. So in certain cases, `ispell` will sort a list of words into a different order than the standard "dictionary" order for the target language.

```
alt-sets : alttype [ alt-stmt*]
```

Because different formatters use different notations to represent non-ASCII characters, `ispell` must be aware of the representations used by these formatters. These are declared as alternate sets of string characters.

```
alttype : altstringtype name suffix*
```

The `altstringtype` statement introduces each set by declaring the associated formatter name and filename suffix list. This name and list are interpreted exactly as in the `defstringtype` statement. Following this header are one or more `alt-stmts` that declare the alternate string characters used by this formatter.

```
alt-stmt : altstringchar alt-string std-string
```

The `altstringchar` statement describes alternate representations for string characters. For example, the `-mm` macro package of `troff` represents the German "a-umlaut" as `a*`, while TeX uses the sequence `\"a`. If the `troff` versions are declared as the standard versions using `stringchar`, the TeX versions may be declared as alternates by using the statement:

```
altstringchar "\\\"a a\**
```

When the `altstringchar` statement is used to specify alternate forms, all forms for a particular formatter must be declared together as a group. Also, each formatter or macro package must provide a complete set of characters, both uppercase and lowercase, and the character sequences used for each formatter must be completely distinct. Character sequences that describe uppercase and lowercase versions of the same printable character must also be the same length. It may be necessary to define some new macros for a given formatter to satisfy these restrictions. (The current version of `buildhash` does not enforce these restrictions, but failure to obey them may result in errors being introduced into files that are processed with `ispell`.)

An important minor point is that `ispell` assumes that all characters declared as `wordchars` or `boundarychars` will occupy exactly one position on the terminal screen.

A single character-set statement can declare either a single character or a contiguous range of characters. A range is given as in `egrep` and the shell: `[a-z]` means lowercase alphabets; `[^a-z]` means all but lowercase, and so on. All character-set statements are combined (unioned) to produce the final list of characters that may be part of a word. The collating order of the characters is defined by the order of their declaration; if a range is used, the characters are considered to have been declared in ASCII order. Characters that have case are collated next to each other, with the uppercase character first.

The character-declaration statements have a rather strange behavior caused by the need to match each lowercase character with its uppercase equivalent. In any given `wordchars` or `boundarychars` statement, the characters in each range are first sorted into ASCII collating sequence, then matched one-for-one with the other range. (The two ranges must have the same number of characters). Thus, for example, the two statements:

```
wordchars [aeiou] [AEIOU]
wordchars [aeiou] [UOIEA]
```

would produce exactly the same effect. To get the vowels to match up “wrong,” you would have to use separate statements:

```
wordchars a U
wordchars e O
wordchars i I
wordchars o E
wordchars u A
```

which would cause uppercase *e* to be *O*, and lowercase *o* to be *e*. This should normally be a problem only with languages that have been forced to use a strange ASCII collating sequence. If your uppercase and lowercase letters both collate in the same order, you shouldn’t have to worry about this “feature.”

The prefixes and suffixes sections have exactly the same syntax, except for the introductory keyword:

```
prefixes : prefixes flagdef*
suffixes : suffixes flagdef*
flagdef : flag [*jU] char : repl *
```

A prefix or suffix table consists of an introductory keyword and a list of flag definitions. Flags can be defined more than once, in which case the definitions are combined. Each flag controls one or more `replS` (replacements), which are conditionally applied to the beginnings or endings of various words.

Flags are named by a single character `char`. Depending on a configuration option, this character can be either any uppercase letter (the default configuration) or any 7-bit ASCII character. Most languages should be able to get along with just 26 flags.

A flag character may be prefixed with one or more option characters. (If you wish to use one of the option characters as a flag character, simply enclose it in double quotes.)

The asterisk (*) option means that this flag participates in cross-product formation. This only matters if the file contains both prefix and suffix tables. If so, all prefixes and suffixes marked with an asterisk will be applied in all cross-combinations to the root word. For example, consider the root *fix* with prefixes *pre* and *in*, and suffixes *es* and *ed*. If all flags controlling these prefixes and suffixes are marked with an asterisk, then the single root *fix* would also generate *prefix*, *prefixes*, *prefixed*, *infix*, *infixes*, *infixed*, *fix*, *fixes*, and *fixed*. Cross-product formation can produce a large number of words quickly, some of which may be illegal, so watch out. If cross-products produce illegal words, `munchlist` will not produce those flag combinations, and the flag will not be useful.

```
repl : condition* > [ - strip-string , ] append-string
```

The `~` option specifies that the associated flag is only active when a compound word is being formed. This is useful in a language like German, in which the form of a word sometimes changes inside a compound.

A `repl` is a conditional rule for modifying a root word. Up to eight conditions may be specified. If the conditions are satisfied, the rules on the rightside of the `repl` are applied, as follows:

1. If a `strip-string` is given, it is first stripped from the beginning or ending (as appropriate) of the root word.
2. The `append-string` is added at that point.

For example, the condition `.` means “any word”, and the condition `Y` means “any word ending in Y.” The following (suffix) replacements:

```
. > MENT
Y > -Y,IES
```

would change *induce* to *inducement* and *fly* to *flies*. (If they were controlled by the same flag, they would also change *fly* to *flyment*, which might not be what was wanted. `munchlist` can be used to protect against this sort of problem; see the command sequence given in the next paragraph.)

No matter how much you might want it, the strings on the right must be strings of specific characters, not ranges. The reasons are rooted deeply in the way `ispell` works, and it would be difficult or impossible to provide for more flexibility. For example, you might want to write:

```
[EY] > -[EY],IES
```

This will not work. Instead, you must use two separate rules:

```
E > -E,IES
Y > -Y,IES
```

The application of `repl`s can be restricted to certain words with conditions:

```
condition : { . | character | range }
```

A condition is a restriction on the characters that adjoin, and/or are replaced by, the right-hand side of the `repl`. Up to eight conditions may be given, which should be enough context for anyone. The right-hand side will be applied only if the conditions in the `repl` are satisfied. The conditions also implicitly define a length; roots shorter than the number of conditions will not pass the test. (As a special case, a condition of a single dot defines a length of zero, so that the rule applies to all words indiscriminately.) This length is independent of the separate test that insists that all flags produce an output word length of at least four.

Conditions that are single characters should be separated by whitespace. For example, to specify words ending in *ED*, write this:

```
E D> -ED,ING # As in covered > covering
```

If you write this:

```
ED > -ED,ING
```

the effect will be the same as

```
[ED] > -ED,ING
```

As a final, minor but important point, it is sometimes useful to rebuild a dictionary file using an incompatible suffix file. For example, suppose you expand the `R` flag to generate “er” and “ers” (thus making the `Z` flag somewhat obsolete). To build a new dictionary `newdict` that using new affixes will accept exactly the same list of words as the old list `olddict` did using old affixes, the `-c` switch of `munchlist` is useful, as in the following example:

```
$ munchlist -c oldaffixes -l newaffixes olddict > newdict
```

If you use this procedure, your new dictionary will always accept the same list the original did, even if you badly screwed up the `affix` file. This is because `munchlist` compares the words generated by a flag with the original word list and refuses to use any flags that generate illegal words. (Don’t forget that the `munchlist` step takes a long time and eats up temporary file space.)

EXAMPLES

As an example of conditional suffixes, here is the specification of the `S` flag from the English `affix` file:

```
flag *S:
[^AEIOU]Y > -Y,IES # As in imply > implies
[AEIOU]Y > S # As in convey > conveys
[SXZH] > ES # As in fix > fixes
[^SXZHY] > S #As in bat > bats
```

The first line applies to words ending in Y but not in vowel-Y. The second takes care of the vowel-Y words. The third then handles those words that end in a sibilant or near-sibilant, and the last picks up everything else.

Note that the conditions are written very carefully so that they apply to disjoint sets of words. In particular, note that the fourth line excludes words ending in Y as well as the obvious SXZH. Otherwise, it would convert “imply” into “implys.”

Although the English `affix` file does not do so, you can also have a flag generate more than one variation on a root word. For example, you could extend the English `R` flag as follows:

```
flag *R:
E > R #As in skate > skater
E > RS # As in skate > skaters
[^AEIOUY] > -Y,IER # As in multiply > multiplier
[^AEIOUY] > -Y,IERS # As in multiply > multipliers
[AEIOUY] > ER # As in convey > conveyer
[AEIOUY] > ERS # As in convey > conveyers
[^EY] > ER # As in build > builder
[^EY] > ERS # As in build > builders
```

This flag would generate both “skater” and “skaters” from “skate.” This capability can be very useful in languages that make use of noun, verb, and adjective endings. For instance, one could define a single flag that generated all the German “weak” verb endings.

Local

lp

`lp`—Line printer devices.

SYNOPSIS

```
#include <linux/lp.h>
```

CONFIGURATION

`lp[02]` are character devices for the parallel line printers; they have major number 6 and minor number 02. The minor numbers correspond to the printer port base addresses 0x03bc, 0x0378, and 0x0278. Usually, they have mode 220 and are owned by root and group `lp`. You can use printer ports either with polling or with interrupts. Interrupts are recommended when high traffic is expected, such as for laser printers. For usual dot matrix printers, polling will usually be enough. The default is polling.

DESCRIPTION

The following `ioctl(2)` calls are supported:

```
int ioctl(int fd, LPTIME, int arg)
```

Sets the amount of time that the driver sleeps before rechecking the printer when the printer’s buffer appears to be filled to `arg`. If you have a fast printer, decrease this number; if you have a slow printer, then increase it. This is in hundredths of a second; the default 2 is 0.05 seconds. It only influences the polling driver.

```
int ioctl(int fd, LPCHAR, int arg)
```

Sets the maximum number of busy-wait iterations that the polling driver does while waiting for the printer to get ready for receiving a character to `arg`. If printing is too slow, increase this number; if the system gets too slow, decrease this number. The default is 1000. It only influences the polling driver.

```
int ioctl(int fd, LPABORT, int arg)
```

If `arg` is 0, the printer driver will retry on errors; otherwise, it will abort. The default is 0.

```
int ioctl(int fd, LPABORTOPEN, int arg)
```

If `arg` is 0, `open(2)` will be aborted on error; otherwise, the error will be ignored. The default is to ignore it.

```
int ioctl(int fd, LPCAREFUL, int arg)
```

If `arg` is 0, then the out-of-paper, offline, and error signals are required to be false on all writes; otherwise, they are ignored. The default is to ignore them.

```
int ioctl(int fd, LPWAIT, int arg)
```

Sets the number of busy-wait iterations to wait before strobing the printer to accept a just-written character and the number of iterations to wait before turning the strobe off again to `arg`. The specification says this time should be 0.5 microseconds, but experience has shown the delay caused by the code is already enough. For that reason, the default value is 0. This is used for both the polling and the interrupt driver.

```
int ioctl(int fd, LPSETIRQ, int arg)
```

This `ioctl()` requires superuser privileges. It takes an `int` containing the new IRQ as argument. As a side effect, the printer is reset. When `arg` is 0, the polling driver will be used, which is also default.

```
int ioctl(int fd, LPGETIRQ, int *arg)
```

Stores the currently used IRQ in `arg`.

```
int ioctl(int fd, LPGETSTATUS, int *arg)
```

Stores the value of the status port in `arg`. The bits have the following meaning:

```
LP_PBUSY
```

Inverted busy input, active high

```
LP_PACK
```

Unchanged acknowledge input, active low

```
LP_POUTPA
```

Unchanged out-of-paper input, active high

```
LP_PSELECD
```

Unchanged selected input, active high

```
LP_PERRORP
```

Unchanged error input, active low

Refer to your printer manual for the meaning of the signals. Note that undocumented bits can also be set, depending on your printer.

```
int ioctl(int fd, LPRESET)
```

Resets the printer. No argument is used.

FILES

```
/dev/lp*
```

AUTHORS

The printer driver was originally written by Jim Weigand and Linus Torvalds. It was further improved by Michael K. Johnson. The interrupt code was written by Nigel Gamble. Alan Cox modularized it. LPCAREFUL, LPABORT, LPGETSTATUS were added by Chris Metcalf.

mem, kmem, port

mem, kmem, port—System memory, kernel memory, and system ports

DESCRIPTION

`mem` is a character device file that is an image of the main memory of the computer. It can be used, for example, to examine (and even patch) the system.

Byte addresses in `mem` are interpreted as physical memory addresses. References to non-existent locations cause errors to be returned.

Examining and patching is likely to lead to unexpected results when read-only or write-only bits are present.

It is typically created by

```
mknod -m 660 /dev/mem c 1 1
chown root.mem /dev/mem
```

The file `kmem` is the same as `mem`, except that the kernel virtual memory rather than physical memory is accessed.

It is typically created by

```
mknod -m 640 /dev/kmem c 1 2
chown root.mem /dev/kmem
```

`port` is similar to `mem`, but the IO ports are accessed.

It is typically created by

```
mknod -m 660 /dev/port c 1 4
chown root.mem /dev/port
```

mouse

`mouse`—Serial mouse interface.

CONFIG

Serial mice are connected to a serial RS232/V24 dialout line; see `cua(4)` for a description.

DESCRIPTION

The pinout of the usual 9 pin plug as used for serial mice is

<i>Pin</i>	<i>Name</i>	<i>Used for</i>
2	RX	Data
3	TX	-12 V, I _{max} = 10 mA
4	DTR	+12 V, I _{max} = 10 mA
7	RTS	+12 V, I _{max} = 10 mA
5	GND	Ground

This is the specification; in fact, 9 V suffices with most mice.

The mouse driver can recognize a mouse by dropping RTS to low. About 14ms later, the mouse will send 0x4D on the data line. After a further 63ms, Microsoft-compatible mice will send 0x33. Other mice send different values.

The relative mouse movement is sent as dx (positive means right) and dy (positive means down). Various mice can operate at different speeds. To select speeds, cycle through the speeds 9600, 4800, 2400, and 1200 bits/sec, each time writing the two characters from the table below and waiting 0.1 seconds. The following table shows available speeds and the strings that select them:

<i>Bits/sec</i>	<i>String</i>
9600	*q
4800	*p
2400	*o
1200	*n

The first byte of a data packet can be used to synchronization purposes.

MICROSOFT PROTOCOL

The Microsoft protocol uses 1 start bit, 7 data bits, no parity, and 1 stop bit at the speed of 1200 bits/sec. Data is sent to RxD in 3-byte packets. The dx and dy movements are sent as two's-complement, 1b (rb) is set when the left (right) button is pressed:

<i>Byte</i>	<i>d6</i>	<i>d5</i>	<i>d4</i>	<i>d3</i>	<i>d2</i>	<i>d1</i>	<i>d0</i>
1	1	lb	rb	dy7	dy6	dx7	dx7
2	0	dx5	dx4	dx3	dx2	dx1	dx0
3	0	dy5	dy4	dy3	dy2	dy1	dy0

Original Microsoft mice have only two buttons. However, there are some three-button mice that also use the Microsoft protocol. Pressing the third button is reported by sending a packet with zero movement and no buttons pressed.

MOUSESYSTEMS PROTOCOL

The MouseSystems protocol uses 1 start bit, 8 data bits, no parity, and 2 stop bits at the speed of 1200 bits/sec. Data is sent to RxD in 5-byte packets. dx is sent as the sum of the two two's-complement values, dy is sent as negated sum of the two two's-complement values. 1b (mb, rb) is cleared when the left (middle, right) button is pressed:

<i>Byte</i>	<i>d7</i>	<i>d6</i>	<i>d5</i>	<i>d4</i>	<i>d3</i>	<i>d2</i>	<i>d1</i>	<i>d0</i>
1	1	?	?	?	?	lb	mb	rb
2	0	dxa6	dxa5	dxa4	dxa3	dxa2	dxa1	dxa0
3	0	dxb6	dxb5	dxb4	dxb3	dxb2	dxb1	dxb0
4	0	dya6	dya5	dya4	dya3	dya2	dya1	dya0
5	0	dyb6	dyb5	dyb4	dyb3	dyb2	dyb1	dyb0

SUN PROTOCOL

The Sun protocol uses 1 start bit, 8 data bits, no parity, and 2 stop bits at the speed of 1200 bits/sec. Data is sent to RxD in 3-byte packets. dx is sent as single two's-complement value, dy as negated two's-complement value. 1b (mb, rb) is cleared when the left (middle, right) button is pressed:

<i>Byte</i>	<i>d7</i>	<i>d6</i>	<i>d5</i>	<i>d4</i>	<i>d3</i>	<i>d2</i>	<i>d1</i>	<i>d0</i>
1	1	?	?	?	?	lb	mb	rb
2	0	dx6	dx5	dx4	dx3	dx2	dx1	dx0
3	0	dy6	dy5	dy4	dy3	dy2	dy1	dy0

MM PROTOCOL

The MM protocol uses 1 start bit, 8 data bits, odd parity, and 1 stop bit at the speed of 1200 bits/sec. Data is sent to RxD in 3-byte packets. *dx* and *dy* are sent as single signed values, the sign bit indicating a negative value. *lb* (*mb*, *rb*) is set when the left (middle, right) button is pressed:

Byte	<i>d7</i>	<i>d6</i>	<i>d5</i>	<i>d4</i>	<i>d3</i>	<i>d2</i>	<i>d1</i>	<i>d0</i>
1	1	?	?	<i>dxs</i>	<i>dys</i>	<i>lb</i>	<i>mb</i>	<i>rb</i>
2	0	<i>dx6</i>	<i>dx5</i>	<i>dx4</i>	<i>dx3</i>	<i>dx2</i>	<i>dx1</i>	<i>dx0</i>
3	0	<i>dy6</i>	<i>dy5</i>	<i>dy4</i>	<i>dy3</i>	<i>dy2</i>	<i>dy1</i>	<i>dy0</i>

null, zero

`null`, `zero`—Data sink.

DESCRIPTION

Data written on a `null` or `zero` special file is discarded.

Reads from the `null` special file always return end of file, whereas reads from `zero` always return `\0` characters.

`null` and `zero` are typically created by

```
mknod -m 666 /dev/null c 1 3
mknod -m 666 /dev/zero c 1 5
chown root.mem /dev/null /dev/zero
```

NOTES

If these devices are not writable and readable for all users, many programs will act strangely.

ram

`ram`—Ram disk device.

DESCRIPTION

ram is a block device to access the ram disk in raw mode.

It is typically created by

```
mknod -m 660 /dev/ram b 1 1
chown root.disk /dev/ram
```

FILES

/dev/ram

sd

sd—Driver for SCSI disk drives.

SYNOPSIS

```
#include <linux/hdreg.h>
```

CONFIG

The block device name has the following form: sd l p, where l is a letter denoting the physical drive, and p is a number denoting the partition on that physical drive. Often, the partition number, p , will be left off when the device corresponds to the whole drive.

SCSI disks have a major device number of 8 and a minor device number of the form $(16 * \text{drive_number}) + \text{partition_number}$, where drive_number is the number of the physical drive in order of detection and partition_number is as follows:

Partition 0	The whole drive
Partitions 1-4	The DOS “primary” partitions
Partitions 5-8	The DOS “extended” (or “logical”) partitions

For example, /dev/sda will have major 8 and minor 0 and will refer to all the first SCSI drives in the system; /dev/sdb3 will have major 8 and minor 19 and will refer to the third DOS “primary” partition on the second SCSI drive in the system.

At this time, only block devices are provided. Raw devices have not yet been implemented.

DESCRIPTION

The following `ioctl`s are provided:

HDDIO_REQ

Returns the BIOS disk parameters in the following structure:

```
struct hd_geometry {
    unsigned char heads;
    unsigned char sectors;
    unsigned short cylinders;
    unsigned long start;
};
```

A pointer to this structure is passed as the `ioctl(2)` parameter.

The information returned in the parameter is the disk geometry of the drive as understood by DOS! This geometry is not the physical geometry of the drive. It is used when constructing the drive's partition table,

BLKGETSIZE

however, and is needed for convenient operation of `fdisk(1)`, `efdisk(1)`, and `lilo(1)`. If the geometry information is not available, zero is returned for all the parameters.

BLKRRPART

Returns the device size in sectors. The `ioctl(2)` parameter should be a pointer to a `long`.

Forces a re-read of the SCSI disk partition tables. No parameter is needed.

The `scsi(4)` `ioctl`s are also supported. If the `ioctl(2)` parameter is required and it is `NULL`, then `ioctl(2)` will return `-EINVAL`.

FILES

`/dev/sd[a-h]`: The whole device

`/dev/sd[a-h][0-8]`: Individual block partitions

st

`st`—SCSI tape device.

SYNOPSIS

```
#include <sys/mtio.h>
int ioctl(int fd, int request [, (void *)arg3])
int ioctl(int fd, MTIOCTOP, (struct mtop *)mt_cmd)
int ioctl(int fd, MTIOCGET, (struct mtget *)mt_status)
int ioctl(int fd, MTIOCPOS, (struct mtpos *)mt_pos)
```

DESCRIPTION

The `st` driver provides the interface to a variety of SCSI tape devices. Currently, the driver takes control of all detected devices of type sequential-access. The `st` driver uses major device number 9.

Each device uses two minor device numbers: a principal minor device number, `n`, assigned sequentially in order of detection, and a no-rewind device number, `(n + 128)`. Devices opened using the principal device number are sent a `REWIND` command when they are closed. Devices opened using the no-rewind device number are not. Options such as density or block size are not coded in the minor device number. These options must be set by explicit `ioctl()` calls and remain in effect when the device is closed and reopened.

Devices are typically created by

```
mknod -m 660 /dev/st0 c 9 0
mknod -m 660 /dev/st1 c 9 1
mknod -m 660 /dev/nst0 c 9 128
mknod -m 660 /dev/nst1 c 9 129
```

There is no corresponding block device. The character device provides buffering and read-ahead by default and supports reads and writes of arbitrary size (limited by the driver's internal buffer size, which defaults to 32768 bytes but can be changed either by using a kernel startup option or by changing a compile-time constant).

Device `/dev/tape` is usually created as a hard or soft link to the default tape device on the system.

ioctlS

The driver supports three `ioctl` requests. Requests not recognized by the `st` driver are passed to the `scsi` driver. The definitions below are from `/usr/include/linux/mtio.h`:

MTIOCTOP: PERFORM A TAPE OPERATION

This request takes an argument of type `(struct mtop *)`. Not all drives support all operations. The driver returns an EIO error if the drive rejects an operation.

```
/* Structure for MTIOCTOP - mag tape op command: */
struct mtop {
short mt_op; /* operations defined below */
int mt_count; /* how many of them */
};
```

Magnetic tape operations:

MTBSF	Backward space over <code>mt_count</code> filemarks.
MTBSFM	Backward space over <code>mt_count</code> filemarks. Reposition the tape to the EOT side of the last filemark.
MTBSR	Backward space over <code>mt_count</code> records (tape blocks).
MTBSS	Backward space over <code>mt_count</code> setmarks.
MTEOM	Go to the end of the recorded media (for appending files).
MTERASE	Erase tape.
MTFSF	Forward space over <code>mt_count</code> filemarks.
MTFSFM	Forward space over <code>mt_count</code> filemarks. Reposition the tape to the BOT side of the last filemark.
MTFSR	Forward space over <code>mt_count</code> records (tape blocks).
MTFSS	Forward space over <code>mt_count</code> setmarks.
MTNOP	No op; flushes the driver's buffer as a side effect. Should be used before reading status with <code>MTIOCGET</code> .
MTOFFL	Rewind and put the drive off line.
MTRESET	Reset drive.
MTRETEN	Retention tape.
MTREW	Rewind.
MTSEEK	Seek to the tape block number specified in <code>mt_count</code> . This operation requires either a SCSI-2 drive that supports the <code>LOCATE</code> command (device-specific address) or a Tandberg-compatible SCSI-1 drive (Tandberg, Archive Viper, Wangtek,...). The block number should be one that was previously returned by <code>MTIOCPOS</code> because the number is device-specific.
MTSETBLK	Set the drive's block length to the value specified in <code>mt_count</code> . A block length of zero sets the drive to variable block size mode.
MTSETDENSITY	Set the tape density to the code in <code>mt_count</code> . Some useful density codes are 18 0x00 Implicit 0x11 QIC-525 0x04 QIC-11 0x12 QIC-1350 0x05 QIC-24 0x13 DDS 0x0F QIC-120 0x14 Exabyte EXB-8200 0x10 QIC-150 0x15 Exabyte EXB-8500
MTWEOF	Write <code>mt_count</code> filemarks.
MTWSM	Write <code>mt_count</code> setmarks.

MTSETDRVBUFFER

Set various drive and driver options according to bits encoded in `mt_count`. These consist of the drive's buffering mode, six Boolean driver options, and the buffer write threshold. These parameters are initialized only when the device is first detected. The settings persist when the device is closed and reopened. A single operation can affect just the buffering mode, just the Boolean options, or just the write threshold.

A value having zeros in the high-order 4 bits will be used to set the drive's buffering mode. The buffering modes are:

- 0 The drive will not report `GOOD` status on write commands until the data blocks are actually written to the medium.
- 1 The drive may report `GOOD` status on write commands as soon as all the data has been transferred to the drive's internal buffer.
- 2 The drive may report `GOOD` status on write commands as soon as all the data has been transferred to the drive's internal buffer and all buffered data from different initiators has been successfully written to the medium.

To control the write threshold, the value in `mt_count` must include the constant `MT_ST_WRITE_THRESHOLD` logically ORed with a block count in the low 28 bits. The block count refers to 1024-byte blocks, not the physical block size on the tape. The threshold cannot exceed the driver's internal buffer size (see the description).

To set and clear the Boolean options, the value in `mt_count` must include the constant `MT_ST_BOOLEAN` logically ORed with whatever combination of the following options is desired. Any options not specified are set `false`. The Boolean options are

MT_ST_BUFFER_WRITES

(Default: `true`) Buffer all write operations. If this option is `false` and the drive uses a fixed block size, then all write operations must be for a multiple of the block size. This option must be set `false` to write reliable multi-volume archives.

MT_ST_ASYNC_WRITES

(Default: `true`) When this option is `true`, write operations return immediately without waiting for the data to be transferred to the drive if the data fits into the driver's buffer. The write threshold determines how full the buffer must be before a new SCSI write command is issued. Any errors reported by the drive will be held until the next operation. This option must be set `false` to write reliable multi-volume archives.

MT_ST_READ_AHEAD

(Default: `true`) This option causes the driver to provide read buffering and read-ahead. If this option is `false` and the drive uses a fixed block size, then all read operations must be for a multiple of the block size.

MT_ST_TWO_FM

(Default: `false`) This option modifies the driver behavior when a file is closed. The normal action is to write a single filemark. If the option is `true`, the driver will write two filemarks and backspace over the second one.

Note that this option should not be set `true` for QIC tape drives because they are unable to overwrite a filemark. These drives detect the end of recorded data by testing for blank tape rather than two consecutive filemarks.

MT_ST_DEBUGGING

(Default: `false`) This option turns on various debugging messages from the driver (effective only if the driver was compiled with `DEBUG` defined).

MT_ST_FAST_EOM

(Default: `false`) This option causes the `MTEOM` operation to be sent directly to the drive, potentially speeding up the operation but causing the driver

to lose track of the current file number normally returned by the `MTIOCGET` request. If `MT_ST_FAST_EOM` is false, the driver will respond to an `MTEOM` request by forward spacing over files.

Example:

```
struct mtop mt_cmd;
mt_cmd.mt_op = MTSETDRVBUFFER;
mt_cmd.mt_count = MT_ST_BOOLEANS |
    MT_ST_BUFFER_WRITES |
    MT_ST_ASYNC_WRITES;
ioctl(fd, MTIOCTOP, &mt_cmd);
```

MTIOCGET: GET STATUS

This request takes an argument of type (`struct mtget *`). The driver returns an EIO error if the drive rejects an operation.

```
/* structure for MTIOCGET - mag tape get status command */
struct mtget {
    long    mt_type;
    long    mt_resid;
    /* the following registers are device dependent */
    long    mt_dsreg;
    long    mt_gstat;
    long    mt_erreg;
    /* The next two fields are not always used */
    daddr_t    mt_fileno;
    daddr_t    mt_blkno;
};
```

The header file defines many values for `mt_type`, but the current driver reports only the generic types `MT_ISSCSI1` (Generic SCSI-1 tape) and `MT_ISSCSI2` (Generic SCSI-2 tape).

`mt_resid` is always zero. (Not implemented for SCSI tape drives.)

`mt_dsreg` reports the drive's current settings for block size (in the low 24 bits) and density (in the high 8 bits). These fields are defined by `MT_ST_BLKSIZE_SHIFT`, `MT_ST_BLKSIZE_MASK`, `MT_ST_DENSITY_SHIFT`, and `MT_ST_DENSITY_MASK`.

`mt_gstat` reports generic (device independent) status information. The header file defines macros for testing these status bits:

<code>GMT_EOF(x)</code>	The tape is positioned just after a filemark (always false after an <code>MTSEEK</code> operation).
<code>GMT_BOT(x)</code>	The tape is positioned at the beginning of the first file (always false after an <code>MTSEEK</code> operation).
<code>GMT_EOT(x)</code>	A tape operation has reached the physical End of Tape.
<code>GMT_SM(x)</code>	The tape is currently positioned at a setmark (always false after an <code>MTSEEK</code> operation).
<code>GMT_EOD(x)</code>	The tape is positioned at the end of recorded data.
<code>GMT_WR_PROT(x)</code>	The drive is write-protected. For some drives this can also mean that the drive does not support writing on the current medium type.
<code>GMT_ONLINE(x)</code>	The last <code>open()</code> found the drive with a tape in place and ready for operation.
<code>GMT_D_6250(x)</code> , <code>GMT_D_1600(x)</code> , <code>GMT_D_800(x)</code>	This generic status information reports the current density setting for 9-track tape drives only.
<code>GMT_DR_OPEN(x)</code>	The drive does not have a tape in place.
<code>GMT_IM_REP_EN(x)</code>	Immediate report mode (not supported).
	<code>mt_erreg</code> : The only field defined in <code>mt_erreg</code> is the recovered error count in the low 16 bits (as defined by <code>MT_ST_SOFTERR_SHIFT</code> and <code>MT_ST_SOFTERR_MASK</code>). Due to inconsistencies in the way drives report recovered errors, this count is often not maintained.

`mt_fileno` reports the current file number (zero-based). This value is set to `-1` when the file number is unknown (such as after `MTBSS` or `MTSEEK`).

`mt_blkno` reports the block number (zero-based) within the current file. This value is set to `-1` when the block number is unknown (such as after `MTBSF`, `MTBSS`, or `MTSEEK`).

MTIOCPOS: GET TAPE POSITION

This request takes an argument of type (`struct mtpos *`) and reports the drive's notion of the current tape block number, which is not the same as `mt_blkno` returned by `MTIOCGET`. This drive must be a SCSI-2 drive that supports the `READ POSITION` command (device-specific address) or a Tandberg-compatible SCSI-1 drive (Tandberg, Archive Viper, Wangtek,...).

```
/* structure for MTIOCPOS - mag tape get position command */
struct mtpos {
    long mt_blkno; /* current block number */
};
```

RETURN VALUE

EIO	The requested operation could not be completed.
ENOSPC	A write operation could not be completed because the tape reached end-of-medium.
EACCES	An attempt was made to write or erase a write-protected tape. (This error is not detected during <code>open()</code> .)
ENXIO	During opening, the tape device does not exist.
EBUSY	The device is already in use or the driver was unable to allocate a buffer.
EOVERFLOW	An attempt was made to read or write a variable-length block that is larger than the driver's internal buffer.
EINVAL	An <code>ioctl()</code> had an illegal argument, or a requested block size was illegal.
ENOSYS	Unknown <code>ioctl()</code> .

tty

`tty`—Controlling terminal.

DESCRIPTION

The file `/dev/tty` is a character file with major number 5 and minor number 0, usually of mode 0666 and owner.group `root.tty`. It is a synonym for the controlling terminal of a process, if any.

In addition to the `ioctl()` requests supported by the device that `tty` refers to, the following `ioctl()` request is supported:

TIOCNOTTY

Detach the current process from its controlling terminal and remove it from its current process group, without attaching it to a new process group (that is, set its process group ID to zero). This `ioctl()` call only works on file descriptors connected to `/dev/tty`; this is used by daemon processes when they are invoked by a user at a terminal. The process attempts to open `/dev/tty`; if the open succeeds, it detaches itself from the terminal by using `TIOCNOTTY`, but if the open fails, it is obviously not attached to a terminal and does not need to detach itself.

FILES

`/dev/tty`

ttys

`ttys`—Serial terminal lines.

DESCRIPTION

`ttys[0-3]` are character devices for the serial terminal lines.

They are typically created by

```
mknod -m 660 /dev/ttyS0 c 4 64 # base address 0x03f8
mknod -m 660 /dev/ttyS1 c 4 65 # base address 0x02f8
mknod -m 660 /dev/ttyS2 c 4 66 # base address 0x03e8
mknod -m 660 /dev/ttyS3 c 4 67 # base address 0x02e8
chown root.tty /dev/ttyS[0-3]
```

FILES

`/dev/ttyS[0-3]`

SEE ALSO

`mknod(1)`, `chown(1)`, `getty(1)`, `tty(4)`

Linux, 19 December 1992

VCS, VCSa

`vcs`, `vcsa`—Virtual console memory.

DESCRIPTION

`/dev/vcs0` is a character device with major number 7 and minor number 0, usually of mode 0644 and owner `root.tty`. It refers to the memory of the currently displayed virtual console terminal.

`/dev/vcs[1-63]` are character devices for virtual console terminals; they have major number 7 and minor number 1 to 63, usually mode 0644 and owner `root.tty`. `/dev/vcsa[0-63]` are the same but include attributes and are prefixed with four bytes, giving the screen dimensions and cursor position: `lines`, `columns`, `x`, `y`. (`x = y = 0` at the top-left corner of the screen.)

These replace the screendump `ioctl`s of `console(4)`, so the system administrator can control access using filesystem permissions.

The devices for the first eight virtual consoles may be created by

```
for x in 0 1 2 3 4 5 6 7 8; do
mknod -m 644 /dev/vcs$x c 7 $x;
mknod -m 644 /dev/vcsa$x c 7 ${x+128};
done
chown root.tty /dev/vcs*
```

No `ioctl`() requests are supported.

EXAMPLES

You can do a screendump on vt3 by switching to vt1 and typing `cat /dev/vcs3 >foo`.

This program displays the character and screen attributes under the cursor of the second virtual console and then changes the background color there:

```
#include <unistd.h>
#include <stdio.h>
#include <fcntl.h>

void main()
{ int fd;
  struct {char lines, cols, x, y;} scrn;
  char ch, attrib;

  fd = open("/dev/vcsa2", O_RDWR);
  (void)read(fd, &scrn, 4);
  (void)lseek(fd, 4 + 2*(scrn.y*scrn.cols + scrn.x), 0);
  (void)read(fd, &ch, 1);
  (void)read(fd, &attrib, 1);
  printf("ch='%c' attrib=0x%02x\n", ch, attrib);
  attrib ^= 0x10;
  (void)lseek(fd, -1, 1);
  (void)write(fd, &attrib, 1);
}
```

FILES

```
/dev/vcs[0-63]
/dev/vcsa[0-63]
```

active, active.times

`active`, `active.times`—List of active Usenet newsgroups.

DESCRIPTION

The file `/news/lib/active` lists the newsgroups that the local site receives. Each newsgroup should be listed only once. Each line specifies one group; their order in the file does not matter. Within each newsgroup, articles are assigned unique names, which are monotonically increasing numbers.

If an article is posted to newsgroups not mentioned in this file, those newsgroups are ignored. If no valid newsgroups are specified, the article is filed into the newsgroup “junk” and only propagated to sites that receive the “junk” newsgroup.

Each line consists of four fields specified by a space:

```
name hi mark l o mark f l a g s
```

The first field is the name of the newsgroup. Newsgroups that start with the three characters `to.` are treated specially; see `innd(8)`. The second field is the highest article number that has been used in that newsgroup. The third field is the lowest article number in the group; this number is not guaranteed to be accurate and should only be taken as a hint. Note that because of article cancellations, there may be gaps in the numbering sequence. If the lowest article number is greater than the highest article number, there are no articles in the newsgroup. To make it possible to update an entry in-place without rewriting the entire file, the second and third fields are padded with leading zeros to make them a fixed width.

The fourth field can contain one of the following flags:

<code>y</code>	Local postings are allowed
<code>n</code>	No local postings are allowed, only remote ones
<code>m</code>	The group is moderated and all postings must be approved
<code>j</code>	Articles in this group are not kept but only passed on
<code>x</code>	Articles cannot be posted to this newsgroup
<code>=foo.bar</code>	Articles are locally filed into the <code>foo.bar</code> group

If a newsgroup has the `j` flag, then no articles will be filed into that newsgroup and local postings to that group should not be generated. If an article for such a newsgroup is received from a remote site, it will be filed into the “junk” newsgroup if it is not cross-posted. This is different from not having a newsgroup listed in the file because sites can subscribe to `j` newsgroups and the article will be propagated to them.

If the fourth field of a newsgroup starts with an equal sign, then the newsgroup is an alias. Articles can be posted to the group but will be treated as if they were posted to the group named after the equal sign. The second and third fields are ignored. Note that the newsgroup header is not modified (Alias groups are typically used during a transition and are typically created with `ctlinnd(8)`). An alias newsgroup should not point to another alias.

The file `/news/lib/active.times` provides a chronological record of when newsgroups are created. This file is normally updated by `inn(8)` whenever a `ctlinnd newgroup` command is done. Each line consist of three fields:

```
name time creator
```

The first field is the name of the newsgroup. The second field is the time it was created, expressed as the number of seconds since the epoch—a `time_t`; see `gettimeofday(2)`. The third field is the electronic mail address of the person who created the group.

HISTORY

adduser.conf

`adduser.conf`—Configuration file for `adduser(8)` and `addgroup(8)`.

SYNOPSIS

```
/etc/adduser.conf
```

DESCRIPTION

The file `adduser.conf` contains defaults for the programs `adduser(8)` and `addgroup(8)`. Each option takes the form `option = value`.

The valid configuration options are

DSHELL	The login shell to be used for all new users. Defaults to <code>/bin/bash</code> .
DHOME	The directory in which new home directories should be created. Defaults to <code>/home</code> .
SKEL	The directory from which skeletal user configuration files should be copied. Defaults to <code>/etc/skel</code> .
FIRST_UID	Specifies the lowest valid UID for normal users on your system. IDs below <code>FIRST_UID</code> are reserved for administrative and system accounts. Defaults to <code>1000</code> .
USERGROUPS	The <code>USERGROUPS</code> variable can be either <code>yes</code> or <code>no</code> . If <code>yes</code> , each created user will be given their own group to use as a default, and their setup will arrange to have them create files group-writable by default, thus allowing them to effectively use group-writable filespace areas (such as <code>/usr/local</code>). If <code>no</code> , each created user will be placed in the group whose GID is <code>USERS_GID</code> , and they will create files not group-writable by default.
USERS_GID	If <code>USERGROUPS</code> is <code>no</code> , then <code>USERS_GID</code> is the GID given to all newly created users. The default value is <code>100</code> .

FILES

```
/etc/adduser.conf
```

SEE ALSO

`adduser(8)`

aliases

`aliases`—Aliases file for `sendmail`.

SYNOPSIS

`aliases`

DESCRIPTION

This file describes user ID aliases used by `.`. The file resides in `.` and is formatted as a series of lines of the form:

```
name: name_1, name_2, name_3, ...
```

The `name` is the name to alias, and the `name_n` are the aliases for that name. Lines beginning with whitespace are continuation lines. Lines beginning with `#` are comments.

Aliasing occurs only on local names. Loops cannot occur because no message will be sent to any person more than once.

After aliasing has been done, local and valid recipients who have a `.forward` file in their home directory have messages forwarded to the list of users defined in that file.

This is only the raw data file; the actual aliasing information is placed into a binary format in the files and using the program `newaliases(1)`. A `newaliases` command should be executed each time the aliases file is changed for the change to take effect.

SEE ALSO

`newaliases(1)`, `dbm(3)`, `sendmail(8)`, “Sendmail Installation and Operation Guide,” “Sendmail: An Internetwork Mail Router.”

BUGS

Because of restrictions in `dbm(3)`, a single alias cannot contain more than about 1000 bytes of information. You can get longer aliases by “chaining”—that is, making the last name in the alias a dummy name that is a continuation alias.

HISTORY

The `aliases` file format appeared in BSD 4.0.

BSD 4, 10 May 1991

cfingerd

`cfingerd`—Configurable finger daemon.

SYNOPSIS

```
cfingerd [-c|-d|-e|-o|-v]
```

<code>-c</code>	Check configuration
<code>-d</code>	Run as daemon, not <code>inetd</code>
<code>-e</code>	Emulate local finger without <code>inetd</code>
<code>-o</code>	Turn off all finger queries
<code>-v</code>	Request version information

`-c` checks your installed configuration. This makes sure there are no existing errors in the current `cfingerd.conf` file.

`-d` runs `cfingerd` as a daemon. Don't run `cfingerd` this way if you're using `inetd`.

`-e` allows you to emulate a local finger on a user that exists on your system. This makes it so that you can test `cfingerd` on your system before installing it. Using the `-e` directive is the same as installing the software, typing `finger username@` and getting the output. Using `-e username` does the same.

- o turns off all finger queries. This makes it so that no one can finger your system—no matter what they try to do.
- v requests cfingerd version information.

DESCRIPTION

cfingerd is a totally new and totally configurable finger daemon—one of the first. It utilizes the finger port (port 79) to provide useful information on each user on your system. However, cfingerd provides a unique twist.

cfingerd was designed for the sole purpose of making output on finger queries configurable. If you want to change any text that is displayed during finger queries, you can configure the finger daemon to display just about anything you want.

cfingerd also takes into account any security breaches and attempts to close them. With .nofinger files, this is displayed instead of finger information, making it possible for users to keep themselves relatively anonymous from outside users.

WHY WAS IT DONE?

The answer is simple: security. Many sites turn off finger for the reason that they don't want outside users to see who's on their system or get information about a specific user on their system. This seemed unfair to the rest of the users out there, so this program was created. Those sites were waiting for this type of program. Many sites that originally had their finger turned off turned them back on because of cfingerd.

Many sites complained that they wanted the capability to create a fake user or a user that doesn't exist but calls a prewritten shell script. cfingerd takes this into account and provides the best method possible for creating such scripts. (See cfingerd.conf(5) for more information on the configuration file.)

FEATURES cfingerd PROVIDES AND DESCRIPTIONS OF EACH

cfingerd was totally rewritten. Why is this? The older version of cfingerd had quite a few bugs, and it didn't quite do all the things that cfingerd now does. This new version was totally revamped, and most of the bugs that were in the older version of cfingerd were removed in this one. The code is also more compact.

Header and footer displays were a big part of the original release of cfingerd and shall continue to remain in all versions. Headers and footers are only displays at the beginning and ending of all finger displays and are used as unique little advertisements.

The last time displayed is always a critical issue. It's covered in cfingerd. cfingerd simply shows how many times this user is connected, what their idle time is on each tty they're connected to, and whether they are accepting messages. If they're not accepting messages, a [MSG-N] display will be shown. This display also shows the last time mail was read and whether this user has mail.

Stand-alone and inetd support is compiled into the program, but only inetd support is given for the time being. The reason is that I have not yet added the option for stand-alone daemon mode.

.nofinger files are used when a user wants to remain anonymous. These files should be placed in their home directories and can display anything they want. There's just a few restrictions. These .nofinger display files cannot be character devices, directories, FIFOs, soft or hard links, or anything else of that caliber. They must only be normal files.

Fake users were supported for the simple fact that many sites want to create users who don't exist and make them execute a shell. If you want this done, install a fake user. Read cfingerd.conf(5) for more information on these useful options.

Service displays were used to show what fake users you have installed on your system. These can be formatted however you want and are explained in cfingerd.conf(5).

Searching for usernames is a powerful feature that cfingerd takes full advantage of. If you are looking for a specific username on the system or don't know what their name is, simply use the search.username directive with cfingerd, and you can search for a user on your system.

Searching for usernames is not case sensitive. If you are searching for a specific username or part of the user's name, chances are that it'll be displayed.

There's also an option to display your public PGP key if you have one. This is very useful if you want to keep your mail or other information secret to yourself and don't want "big brother" watching over your shoulder as you talk among yourselves. (Thanks to Andy Smith for this patch.) The standard plan file is `.plan`, project is `.project`, and PGP info is `.pgpkey`.

Remember, any or all of these options stated can be turned on or off at will. If you want a specific option turned off, turn it off.

ERROR MESSAGES

Any error messages that result are fairly easy to debug if you know what to look for.

Segmentation violations don't always occur, but if they ever do, you can pretty easily figure out what's going on. Unfortunately, `cfingerd` doesn't have any compatibility with older `cfingerd.conf` files, so if you get a segmentation violation, this means (usually) that your `cfingerd.conf` file needs to be replaced.

Time-outs usually mean that a script has timed out or a connection to another site timed out.

SYSLOGGING MESSAGES

There's no real way to describe `SYSLOG` messages because they can be changed as the system administrator chooses. Although, examples can be given based on the standard configuration that was distributed.

If any IP addresses cannot be matched to a hostname, `SYSLOG` will display `IP: Hostname not matched`.

If the `renice` fails (to make the program run at the highest priority), then `SYSLOG` will display `Fatal - Nice died: (reason)`.

If there is no buffer information is waiting in the `STDIN` buffer, `SYSLOG` will display `STDIN contains no data`.

If a trusted host fingers your site, a `<- Trusted` will appear.

If a rejected host fingers your site, a `<- Rejected` will appear.

If root is fingered on your site, it will display `Root`.

If a service listing was fingered on your site, `SYSLOG` will display `Service listing`.

If a user listing was requested, `SYSLOG` will display `User listing`.

If a fake user was requested, `SYSLOG` will display `Fake user`.

If whois data was requested, `SYSLOG` will display `Whois request`. (Note that whois was not implemented in this release because it wasn't RFC compliant.)

Any extra information pertaining to the incoming finger is displayed in the `syslogging` area. (It's also recommended that you reconfigure `syslog.conf(5)` to display to an unused VT.)

BUGS

When data is forwarded to other sites for fingering, it shows the output of the system that it forwarded the finger request to. This has got to change.

On ELF-specific systems, services lists usually show a bit of garbage at the beginning of the finger display. This doesn't appear to be a problem on `a.out` systems, so if you have ELF, you might want to compile `cfingerd` as `a.out` if this becomes a problem.

PLANS

Any other options or improvements will probably come from user suggestions.

Later plans will mean you can define your own display formats for the finger display. This means that you can redefine how you want your finger display to look.

CONTACTING

If you like the software and you want to learn more about it or want to see a feature added to it that isn't already here, write to khollis@bitgate.com.

I've received calls at work pertaining to the software, and although I appreciate the fact that people like the software I wrote, I'd appreciate it if you leave me e-mail and be considerate.

cfingerd is now being maintained by Michael Jarvis. Any additions after cfingerd 1.2.3 should be directed toward Michael. You can reach him at mjarvis@qns.com.

If you want to see other projects that Bitgate Software is currently developing, check out the Web page at <http://www.bitgate.com/>. This will contain all the update information on the software that is being developed and that is already released.

cfingerd 1.2.3, 24 May 1996

cfingerd.conf

cfingerd.conf—Configurable finger daemon configuration file.

SYNOPSIS

`/etc/cfingerd.conf`

DESCRIPTION

cfingerd.conf is the configuration file for cfingerd. This has been totally rewritten to support a more readable configuration file. This version of the new configuration file is not compatible with the older versions from 1.0.3 or earlier.

Each line in the configuration file is split into three sections: FILES, CONFIG, and HOSTS. Each one of those sections is split into subsections.

Subtext of each option is either Boolean options, string options, or switchable options, all changeable by the system administrator.

Each section is split into a series of sections that resembles C-type definition; it's not exact but close enough to be familiar. There's only one exception: These are not case sensitive. Any casing will do as long as the option is legal.

Thus, each option is formatted like this:

```
OPTION sub_option_name = {
(tab/space) string_option = "string format",
(tab/space) boolean_option = [BOOL, BOOL],
(tab/space) +/-internal_config_option
(tab/space) host.name.here
}
```

This shows that string options are strings put into quotes, Boolean options are given as TRUE and FALSE, switchable options are given with the + or - directive, and hostnames are used as substrings so that wildcards are not necessary.

You can add comments using the hash mark (#) at the beginning of the line. Please note that no comments are allowed inside of an OPTION.

DISPLAY FILES SECTION (FILES display files)

Each option here is a string option. These are formatted as the example shows.

PLAN is the plan file that is used when displaying a plan. The standard here is .plan.

PROJECT is the project file that is used when displaying a project description. The standard here is .project.

PGP_KEY is the Pretty-Good-Privacy file that is shown when displaying a public or private key. The standard here is .pgpkey.

(The preceding three files must be world readable but should not be world writable. This makes sure that `cfingerd` can read the file once it becomes the “nobody” UID/GID. This is generally a good idea for protection.)

`NO_FINGER` is the file that is shown when a user wants to remain anonymous. This is usually the case with root users (which should be standard anyway). The standard here is `.nofinger`. This file can only be a standard displayable file.

`LOGFILE` is the file that is used to keep logs of everything that happens to both your system and the finger program. These logs are kept as backups for your finger file and can be used to guard against attacks against your system if a finger attack occurs. Remember, the `cfingerd.conf` file is root owned, so this file should be kept in a safe, hidden place.

`HEADER_DISPLAY` is the file that is displayed at the top of each finger display. The standard here is `/etc/cfingerd/top_finger.txt`.

`FOOTER_DISPLAY` is the file that is displayed at the end of each finger display. The standard here is `/etc/cfingerd/bottom_finger.txt`.

`NO_USER_BANNER` is the file that is displayed if the user doesn’t exist. The standard here is `/etc/cfingerd/nouser_banner.txt`.

`NO_NAME_BANNER` is the file that is displayed if no name was specified in a finger display. This is used in conjunction with the `SYSTEM_LIST` option (explained later). The standard here is `/etc/cfingerd/noname_banner.txt`.

`REJECTED_BANNER` is the file that is displayed if a rejected host tries to finger your system for any reason. The standard here is `/etc/cfingerd/rejected_banner.txt`.

FINGER DISPLAY CONFIGURE SECTION (CONFIG finger display)

Each option in this section is Boolean. The way this works is as follows: The first Boolean option is the setting for a remote host or a host that fingers you from the outside. The second Boolean option is the setting for the local host or trusted host. This is what people from your own system will see.

Each option has a - or + option. This is for user-overrideable options, which will be in the next release of `cfingerd`. These will allow users to manipulate if this information is displayed when that specific user is fingered.

`HEADER_FILE` displays the header file at the beginning of each finger query.

`FOOTER_FILE` displays the footer file at the end of each finger query.

`LOGIN_ID` displays the login ID of that particular user.

`REAL_NAME` displays the real name of that particular user.

`DIRECTORY` displays the user’s directory.

`SHELL` displays the user’s shell.

`ROOM_NUMBER` displays the user’s room number.

`WORK_NUMBER` displays the user’s work phone number.

`HOME_NUMBER` displays the user’s home phone number.

`OTHER` displays the user’s other information.

`LAST_TIME_ON` displays the last time the user logged into the fingered system.

`IF_ONLINE` displays whether the user is currently logged into the fingered system.

`TIME_MAIL_READ` displays the last time that the fingered user read mail.

`DAY_MAIL_READ` displays the last day that the fingered user read his or her mail.

`ORIGINATION` displays the site from which the user logged in (if applicable).

`PLAN` displays the user’s plan file.

`PROJECT` displays the user’s project file.

`PGP` displays the user’s Pretty-Good-Privacy key file.

`NO_NAME_BANNER` displays the banner if no username was given.

`REJECTED_BANNER` displays the rejected banner if the site fingering your system was in the banned-site listing.

`SYSTEM_LIST` displays the system list if one was requested.

`NO_NAME` displays the no-name display file if no user was selected.

INTERNAL CONFIG CONFIGURE SECTION (CONFIG internal config)

Each item in this section is a switchable option. This means that a + before the item is turned on and a - before the item is turned off.

`ALLOW_MULTIPLE_FINGER_DISPLAY` allows you to give a sorted output of all users on more than one specific system. This is useful when you have more than one ISP machine, located in different cities or even states.

`ALLOW_SEARCHABLE_FINGER` allows you to let others outside your system (or within it) to search for a specific username by using the `search.username` directive.

`ALLOW_NO_IP_MATCH_FINGER` allows you to let sites finger your system if a hostname could not be matched to their IP address successfully.

`ALLOW_USER_OVERRIDE` will allow your users to override specific options in the `FINGER_DISPLAY` section that you enable.

`ALLOW_USERLIST_ONLY` will allow other sites that are fingering your system for a specific compiled user list to finger your system and get a user listing of who's online. This could be a security risk, so you might want to turn this option off if you feel it's a security risk.

`ALLOW_FINGER_FORWARDING` will allow other sites to forward finger requests to a different machine if the user could not be located on the current machine. (In order to use this option, you must have the `HOSTS_finger` forward option set and have other sites in there.)

`ALLOW_STRICT_FORMATTING` makes the finger display remove all returns between display options. This makes the finger display look horrible (as with GNU Finger or the other generic fingers) and makes your system look, well, "generic."

`ALLOW_VERBOSE_TIMESTAMPING` makes the timestamp that is displayed (at any place) very verbose. For instance, where it used to say

```
On since Sat Aug 12 03:43PM(PDT)
```

would now be shown as

```
On since Sat Aug 12, 1995 03:43PM(PDT)
```

(Basically, `ALLOW_VERBOSE_TIMESTAMPING` just takes up more room on the display field.)

`ALLOW_NONIDENT_ACCESS` lets you only allow connections from sites that run the `ident` daemon (or RFC 1413-compliant program.) This is for security sake and is a good measure against unknown users trying to finger your system. If this option is enabled, users who do not have `identd` running on their system (such as Windows users) will be able to finger your system. Systems not running `identd` will return `unknown` as the user ID and will not be permitted to finger a user on your system.

`ALLOW_FINGER_LOGGING` enables `cfingerd` to use the `LOGFILE` file to store any logs of activity that happen to your system via finger.

`ALLOW_LINE_PARSING` makes `cfingerd` parse each line of every display file (including the `plan`, `project`, and `pgp` files) for any `cfingerd`-specific \$ commands. If any are found, `cfingerd` will parse these commands and display correct information accordingly. Otherwise, if this is turned off, the display will appear without parsed commands.

`ALLOW_EXECUTION` will allow users to execute scripts in place of their `.plan`, `.project`, and `.pgp` files. This is used to display the standard output of another program directly to the screen of the user. Keep in mind that this is a huge security risk if you choose to use it. It's normally suggested that this option remain off, but you can turn it on if necessary. Nevertheless, these programs are called as `nobody.nogroup`.

`ALLOW_FAKEUSER_FINGER` turns on or off the fake user option in `cfingerd`. If you want fake users to be defined and available to be fingered, you will want to enable this option. This can be a security risk in some instances if you allow for searchable fingers and your script calls an execute routine on that variable. Chances are that'll never happen.

`ALLOW_USERLOG` will allow users to keep track of who has fingered them and at what time. A little file called `.fingerlog` will appear in their directory, which they can examine to see who has fingered them. If you don't care about this, you can disable it. Otherwise, it's not a bad idea. (It also logs root fingers as well.)

SYSTEM LIST SITES CONFIGURE SECTION (CONFIG system list sites)

This is just a series of hostnames that you want to finger when displaying your user-list display. If you have more than one system that you want to show, simply put their hostname in this list, separated on a line by itself.

For example, if I have a separate ISP system that I'm running on the side, say `chatlink.com`, I would change my configuration to say

```
CONFIG system_list_sites = { chatlink.com, localhost }
```

Remember, if you are listing only a couple of sites, list the sites you will want to have listed (in order) first. The ending entry must be `localhost` or the finger listing will not include your site. If you include `localhost` anywhere else in the list, it will stop once it has reached the `localhost` entry, so remember to list it last!

I want to get a user listing from my own machine and from `chatlink.com`'s system. This would be automatically formatted nicely (sorted and parsed) and would display on the screen in sorted order. This program is usually used in tandem with the supplied `userlist(1)` program.

If no system list sites are specified, multiple system sites will not be specified.

TRUSTED HOST SECTION (HOSTS trusted)

This is a listing of the sites that you allow to finger your system exclusively, giving them the same access that your local users would get. In other words, they are treated as `localhost` users.

Each site that you list in this section should be separated by using the `,` directive. You can include up to 80 sites in this listing.

Wildcards are supported in this section, and you can use them in the regex format as well. Any wildcards with `*`, `?`, or any other regex wildcard matching character will work. IP addresses will also work. Hostnames are compared case insensitive.

REJECTED HOST SECTION (HOSTS rejected)

This is a listing of the sites that you do not allow to finger your system. These sites don't get to finger anyone (or anything for that matter) on your system, regardless of what they try to do. In essence, finger is cut off to that particular system.

Each site that you list in this section should be separated by using the `,` directive. You can include up to 80 sites in this listing.

Wildcards are supported in this section, and you can use them in the regex format as well. Any wildcards with `*`, `?`, or any other regex wildcard matching character will work. IP addresses will also work. Hostnames are compared case insensitive.

FORWARDED HOST SECTION (HOSTS finger forward)

This is a listing of sites that are used to forward a finger query to when a finger request was processed but that particular user was not found on the associated system. It will step through this listing, and it will search for the user in question. If the user could not be found, then it will step through to the next host and the next, until it finds one.

Each site that you list in this section should be separated by using the `,` directive. You can include up to 80 sites in this listing.

Wildcards are supported in this section, and you can use them in the regex format as well. Any wildcards with `*`, `?`, or any other regex wildcard matching character will work. Hostnames are compared case insensitive.

If you do not specify any forwarding sites in this section, finger forwarding will be disabled for your system.

FINGER STRINGS CONFIGURE SECTION (CONFIG finger strings)

Each option in this section is a string that can be changed to fit your needs when displaying finger information. These strings are limited to about 20 characters on the display. (If you use more than 20, the finger display will end up looking strange.)

USER_NAME is the string that is displayed when the user's username is shown.

REAL_NAME is the string that is displayed when the user's real name is shown.

DIRECTORY is the string that is displayed when the user's directory is shown.

SHELL is the string that is displayed when the user's shell is shown.

ROOM_NUMBER is the string that is displayed when the user's room number is shown.

WORK_NUMBER is the string that is displayed when the user's work phone number is shown.

HOME_NUMBER is the string that is displayed when the user's home phone number is shown.

OTHER is the string that is displayed when the user's other display information is shown.

PLAN is the string that is displayed when the user's plan is shown.

PROJECT is the string that is displayed when the user's project is shown.

PGPKEY is the string that is displayed when the user's PGP key is shown.

NO_PLAN is the string that is displayed when the user doesn't have a plan file to show you.

NO_PROJECT is the string that is displayed when the user doesn't have a project file to show you.

NO_PGP is the string that is displayed when the user doesn't have a PGP key file to show you.

WAIT is the string that is shown when the system gathers information from other sites for a user listing.

INTERNAL STRINGS CONFIGURE SECTION (CONFIG internal strings)

These strings are changeable and can be any length you want (within reason). These strings are concatenated into the syslogging display when the appropriate finger has been issued. This section also includes error messages that may occur.

NO_IP_HOST is shown when there is no hostname that matches the incoming IP address. This usually indicates that either the site didn't register its IP address with the InterNIC or it is coming from a hacked site.

RENICE_FATAL is shown when the system failed to change the execution priority on the current process of cfingerd.

STDIN_EMPTY is shown when the input buffer on the cfingerd port is empty. (This should never really happen; it's here for sanity.)

TRUSTED_HOST is shown when a trusted host fingers your system. If you do not specify a trusted host, cfingerd will insert local host into this field.

REJECTED_HOST is shown when a rejected host fingers your system. If you do not specify a rejected host, cfingerd will insert 0.0.0.0 into this field.

ROOT_FINGER is shown when a user fingers root.

SERVICE_FINGER is shown when a user requests fake user services from your system.

USER_LIST is shown when a user requests a user listing from your system.

FAKE_USER is shown when a user fingers a fake user from your system.

WHOIS_USER is shown when a user fingers a user with a WHOIS query. (This option is not yet available.)

FINGER_DENY is shown when a user tries to finger with a forward request such as user@host1@host2. This is not supported because it could result in finger loops and a lot of traffic.

SIGNAL STRINGS CONFIGURE SECTION (CONFIG signal strings)

This section is used in changing the output that is given when a system crashes, or a signal is caught, and reported to the finger output.

The supported caught signals are as follows:

SIGHUP, SIGINT, SIGQUIT, SIGILL, SIGTRAP, SIGABRT, SIGFPE, SIGUSR1, SIGSEGV, SIGUSR2, SIGPIPE, SIGALRM, SIGTERM, SIGCONT, SIGTSTP, SIGTTIN, SIGTTOU, SIGIO, SIGXCPU, SIGXFSZ, SIGVTALRM, SIGPROF, SIGWINCH

FINGER PROGRAMS FILES SECTION (FILES finger programs)

These are the programs that are called when a specific action is taken on the finger display.

`FINGER` is the file that is used when a user listing is requested from your machine. This is used in the standard user list and in the sorted user list, so it is wise to use the standard here: `/usr/sbin/userlist`.

`WHOIS` is the program that is used when a `WHOIS` request is done on a specific user.

FINGER FAKE USERS FILES SECTION (FILES finger fakeusers)

These are the ever-popular fake users that you can create on your system. These users are ones that don't exist (and should not exist, for that matter). These are, instead, treated as normal scripts that can be called for your use.

The format is as follows for fake users:

```
fake_username Script_name SEARCHBOOL script
```

`fake_username` is the name of the fake user you want to request. Make sure that this is a user that does not exist on your system. Keep in mind that if you create a fake username and that user already exists, the fake username will be shown.

`Script_name` is the standard name of your script. This is used in the display of your services listing.

`SEARCHBOOL` specifies whether parameters can be sent to that specific fake user. If you decide to use the `SEARCHBOOL` option (`TRUE` in this case), the passed variables are

```
$1           First passed option
$2           Second passed option
$3           Third passed option
$4           Fourth passed option
```

(If more than four options were passed to this, the request will be ignored, and an error message will be returned to the user who requested the finger request.)

`script` is the location of your script. It should be `chmod 700` and readable only by root.

If you do not specify any fake users, a fake user called `None` will be created. This is a fake user that does nothing and calls `/dev/null` for the script.

SERVICES HEADER CONFIGURE SECTION (CONFIG services header)

This is the display that is given during a services finger. It should be formatted the same way that you want it to display on the screen.

When specifying the finger formatted options, you should specify them as C formatted strings as well, with the standard options. This should always be given last in the display.

An example of this is

```
Welcome to this system's services!
User: Service name: Searchable:
-----
%-8s %-20s %-s
```

Remember to keep the format string last or a `SIGSEGV` will result.

SERVICES POSITIONS CONFIGURE SECTION (CONFIG services positions)

This specifies where in the preceding display string that the information from a service listing is to appear. These numbers can be anywhere between 1 and 3.

USER specifies the position of the username listing.

SERVICE specifies the position of the service full-name listing.

SEARCH specifies the position of the Boolean search display.

CONTACTING

If you like this program and have questions or comments about the program's functionality or what-have-you, write to khollis@bitgate.com.

As always, I appreciate any suggestions or bug reports you might have, so bring them on!

cfingerd text rules

EXPLANATION

`cfingerd` offers different commands that can be placed in text files to display corresponding information. Each command used with `cfingerd` in text files begins with a dollar sign (`$`). This usually indicates to `cfingerd` that when it's displaying a file, it parses the command directly after that character.

If you want to display a raw `$` sign, simply put two `$` signs together, or `$$`.

TEXT COMMANDS

The following is a list of text commands and what they do. Each of the text commands can be in any text case; it doesn't matter.

<code>\$CENTER</code>	Displays the entire contents of the line. This command must start at the beginning of the line. This is a very common command.
<code>\$DATE</code>	Displays the current system date in the format of MM/DD/YY.
<code>\$TIME</code>	Displays the current system time in the format HH:MM A/PM (time zone).
<code>\$IDENT</code>	Displays the identity of the current person fingering your system.
<code>\$COMPILE_DATETIME</code>	Displays the date and time of which the current issue of <code>cfingerd</code> was compiled on your system.
<code>\$VERSION</code>	Displays the current version of <code>cfingerd</code> .
<code>\$EXEC</code>	Executes a file with <code>x</code> parameters after it. The <code>SEXEC</code> command must be on a line by itself in order to function properly. The command is executed as <code>nobody.nogroup</code> .

`cfingerd 1.2.1`, 6 Jan 1996

control.ctl

`control.ctl`—Specify handling of Usenet control messages.

DESCRIPTION

The file `/news/lib/control.ct1` is used to determine what action is taken when a control message is received. It is read by the `parsecontrol` script, which is called by all the control scripts. (For an explanation of how the control scripts are invoked, see `innd(8)`.)

The file consists of a series of lines; blank lines and lines beginning with a number sign (`#`) are ignored. All other lines consist of four fields separated by a colon:

```
message:from:newsgroups:action
```

The first field is the name of the message for which this line is valid. It should be either the name of the control message, or the word `all` to mean that it is valid for all messages.

The second field is a shell-style pattern that matches the e-mail address of the person posting the message. (The poster's address is first converted to lowercase.) The matching is done using the shell's case statement; see `sh(1)` for details.

If the control message is `newgroup` or `rmgroup`, then the third field specifies the shell-style pattern that must match the group being created or removed. If the control message is of a different type, then this field is ignored.

The fourth field specifies what action to take if this line is selected for the message. The following actions are understood:

<code>doit</code>	The action requested by the control message should be performed. In most cases, the control script will also send mail to Usenet.
<code>doifarg</code>	If the control message has an argument, this is treated as a <code>doit</code> action. If no argument was given, it is treated as a <code>mail</code> entry. This is used in a <code>sendsys</code> entries script so that a site can request its own <code>newsfeeds(5)</code> entry by posting a <code>sendsys</code> <code>mysite</code> article. On the other hand, <code>sendsys</code> <code>bombs</code> ask that the <code>newsfeeds</code> file be sent; if you use <code>doifarg</code> , such messages will not be processed automatically.
<code>doit=file</code>	The action is performed, but a log entry is written to the specified log file, <code>file</code> . If <code>file</code> is the word <code>mail</code> , then the record is mailed. A null string is equivalent to <code>/dev/null</code> . A pathname that starts with a slash is taken as the absolute filename to use as the log. All other pathnames are written to <code>/var/log/news/file.log</code> . The log is written by <code>writelog</code> (see <code>newslog(8)</code>).
<code>drop</code>	No action is taken; the message is ignored.
<code>log</code>	A one-line log notice is sent to standard error. <code>innd</code> normally directs this to the file <code>/var/log/news/errlog</code> .
<code>log=file</code>	A log entry is written to the specified log file, <code>file</code> , which is interpreted as described previously.
<code>mail</code>	A mail message is sent to the news administrator.

Lines are matched in order; the last match found in the file is the one that is used. For example, with the following three lines:

```
newgroup:*:*:drop
newgroup:tale@*.uu.net:comp.*|misc.*|news.*|rec.*|sci.*|soc.*|talk.*:doit
newgroup:kre@munnari.oz.au:aus.*:mail
```

A `newgroup` coming from `tale` at a UUNET machine will be honored if it is in the mainstream Usenet hierarchy. If `kre` posts a `newgroup` message creating `aus.foo`, then `mail` will be sent. All other `newgroup` messages are ignored.

HISTORY

$CVSROOT/CVSROOT/taginfo,v
```

DESCRIPTION

`cvs` is a system for providing source control to hierarchical collections of source directories. Commands and procedures for using `cvs` are described in `cvs(1)`. `cvs` manages source repositories, the directories containing master copies of the revision-controlled files, by copying particular revisions of the files to (and modifications back from) developers' private working directories. In terms of file structure, each individual source repository is an immediate subdirectory of `$CVSROOT`. The files described here are supporting files; they do not have to exist for `cvs` to operate, but they allow you to make `cvs` operation more flexible.

You can use the `modules` file to define symbolic names for collections of source maintained with `cvs`. If there is no `modules` file, developers must specify complete pathnames (absolute or relative to `$CVSROOT`) for the files they want to manage with `cvs` commands. You can use the `commitinfo` file to define programs to execute whenever `cvs commit` is about to execute. These programs are used for "precommit" checking to verify that the modified, added, and removed files are really ready to be committed. Some uses for this check might be to turn off a portion (or all) of the source repository from a particular person or group or perhaps to verify that the changed files conform to the site's standards for coding practice.

You can use the `cvswrappers` file to record `cvs` wrapper commands to be used when checking files into and out of the repository. Wrappers allow the file or directory to be processed on the way in and out of `cvs`. The intended uses are many; one possible use is to reformat a C file before the file is checked in so all the code in the repository looks the same. You can use the `logininfo` file to define programs to execute after any commit, which writes a log entry for changes in the repository. These logging programs might be used to append the log message to a file or send the log message through electronic mail to a group of developers. You can also post the log message to a particular newsgroup.

You can use the `taginfo` file to define programs to execute after any `tag` or `rtag` operation. These programs might be used to append a message to a file listing the new tag name and the programmer who created it, to send mail to a group of developers, or to post a message to a particular newsgroup. You can use the `rcsinfo` file to define forms for log messages. You can use the `editinfo` file to define a program to execute for editing or validating `cvs commit` log entries. This is most useful when used with a `rcsinfo` forms specification because it can verify that the proper fields of the form were filled in by the user committing the change. You can use the `cvsignore` file to specify the default list of files to ignore during update. You can use the `history` file to record the `cvs` commands that affect the repository. The creation of this file enables history logging.

FILES

`modules`

The `modules` file records your definitions of names for collections of source code. `cvs` will use these definitions if you use `cvs` to check in a file with the right format to `$CVSROOT/CVSROOT/modules,v`. The `modules` file can contain blank lines and comments (lines beginning with `#`) as well as module definitions. Long lines can be continued on the next line by specifying a backslash (`\`) as the last character on the line. A module definition is a single line of the `modules` file in either of two formats. In both cases, `mname` represents the symbolic module name, and the remainder of the line is its definition.

```
mname -a aliases ...
```

This represents the simplest way of defining a module `mname`. The `-a` flags the definition as a simple alias: `cvs` will treat any use of `mname` (as a command argument) as if the list of names `aliases` had been specified instead. `aliases` may

contain either other module names or paths. When you use paths in `aliases,cvs`, `checkout` creates all intermediate directories in the working directory, just as if the path had been specified explicitly in the `cvs` arguments.

```
mname [ options ] dir [ files ... ] [&module ...]
```

In the simplest case, this form of module definition reduces to `mname dir`. This defines all the files in directory `dir` as module `mname`. `dir` is a relative path (from `$CVSR00T`) to a directory of source in one of the source repositories. In this case, on checkout, a single directory called `mname` is created as a working directory; no intermediate directory levels are used by default, even if `dir` was a path involving several directory levels. By explicitly specifying files in the module definition after `dir`, you can select particular files from directory `dir`. The sample definition for modules is an example of a module defined with a single file from a particular directory. Here is another example:

```
m4test unsupported/gnu/m4 foreach.m4 forloop.m4
```

With this definition, executing `cvs checkout m4test` will create a single working directory `m4test` containing the two files listed, which both come from a common directory several levels deep in the `cvs` source repository. A module definition can refer to other modules by including `&module` in its definition. The `checkout` command creates a subdirectory for each such module in your working directory. New in `cvs` 1.3; avoid this feature if sharing module definitions with older versions of `cvs`.

Finally, you can use one or more of the following options in module definitions:

- `-d name` names the working directory something other than the module name. This option is new in `cvs` 1.3; avoid this feature if sharing module definitions with older versions of `cvs`.
- `-i prog` allows you to specify a program `prog` to run whenever files in a module are committed. `prog` runs with a single argument, the full pathname of the affected directory in a source repository. The `commitinfo`, `loginfo`, and `editinfo` files provide other ways to call a program on `commit`.
- `-o prog` allows you to specify a program `prog` to run whenever files in a module are checked out. `prog` runs with a single argument, the module name.
- `-e prog` allows you to specify a program `prog` to run whenever files in a module are exported. `prog` runs with a single argument, the module name.
- `-t prog` allows you to specify a program `prog` to run whenever files in a module are tagged. `prog` runs with two arguments: the module name and the symbolic tag specified to `rtag`.
- `-u prog` allows you to specify a program `prog` to run whenever `cvs update` is executed from the top-level directory of the checked-out module. `prog` runs with a single argument, the full path to the source repository for this module.

`commitinfo`, `loginfo`, `rcsinfo`, `editinfo`

These files all specify programs to call at different points in the `cvs` `commit` process. They have a common structure. Each line is a pair of fields: a regular expression, separated by whitespace from a filename or command-line template. Whenever one of the regular expression matches a directory name in the repository, the rest of the line is used. If the line begins with a `#` character, the entire line is considered a comment and is ignored. Whitespace between the fields is also ignored. For `loginfo`, the rest of the line is a command-line template to execute. The templates can include not only a program name, but also whatever list of arguments you want. If you write `%s` somewhere on the argument list, `cvs` supplies, at that point, the list of files affected by the `commit`. The first entry in the list is the relative path within the source repository where the change is being made. The remaining arguments list the files that are being modified, added, or removed by this `commit` invocation. For `taginfo`, the rest of the line is a command-line template to execute. The arguments passed to the command are,

in order, the `tagname`, operation (add for tag, mov for tag -F, and del for tag -d), and `repository`, and any remaining are pairs of filename revision. A nonzero exit of the filter program will cause the tag to be aborted. For `commitinfo`, the rest of the line is a command-line template to execute. The template can include not only a program name but also whatever list of arguments you want. The full path to the current source repository is appended to the template, followed by the filenames of any files involved in the commit (added, removed, and modified files). For `rcsinfo`, the rest of the line is the full path to a file that should be loaded into the log message template. For `editinfo`, the rest of the line is a command-line template to execute. The template can include not only a program name but also whatever list of arguments you want. The full path to the current log message template file is appended to the template. You can use one of two special strings instead of a regular expression: `ALL` specifies a command-line template that must always be executed, and `DEFAULT` specifies a command-line template to use if no regular expression is a match. The `commitinfo` file contains commands to execute before any other commit activity, to allow you to check any conditions that must be satisfied before commit can proceed. The rest of the commit will execute only if all selected commands from this file exit with exit status 0. The `rcsinfo` file allows you to specify log templates for the commit logging session; you can use this to provide a form to edit when filling out the commit log. The field after the regular expression, in this file, contains filenames (of files containing the logging forms) rather than command templates. The `editinfo` file allows you to execute a script before the commit starts but after the log information is recorded. These “edit” scripts can verify information recorded in the log file. If the edit script exits with a nonzero exit status, the commit is aborted. The `loginfo` file contains commands to execute at the end of a commit. The text specified as a commit log message is piped through the command; typical uses include sending mail, filing an article in a newsgroup, or appending to a central file.

`cvsignore`, `.cvsignore`

The default list of files (or `sh(1)` filename patterns) to ignore during `cv`s update. At startup time, `cv`s loads the compiled default list of filename patterns (see `cv`s(1)). Then the per-repository list included in `$CVSROOT/CVSROOT/cvsignore` is loaded, if it exists.

Then the per-user list is loaded from `$HOME/.cvsignore`. Finally, as `cv`s traverses through your directories, it will load any per-directory `.cvsignore` files whenever it finds one. These per-directory files are only valid for exactly the directory that contains them, not for any subdirectories.

`history`

Create this file in `$CVSROOT/CVSROOT` to enable history logging (see the description of `cv`s history).

DEVINFO

DEVINFO—Device entry database.

DESCRIPTION

DEVINFO is a text file that describes all the possible devices for a system. It is used by MAKEDEV(8) to create special file entries in `/dev`. It may be named either `/dev/DEVINFO` or `/etc/devinfo`. Information about custom local devices, if any, should be placed in `DEVINFO.local` or `/etc/devinfo.local`, which has the same syntax.

The file format is free-form. C, C++, and shell comments are understood. There are basically four statements:

<code>ignore { proc-device... }</code>	This causes the specified names to be ignored if found in <code>/proc/devices</code> .
<code>batch { device... }</code>	This creates a “batch”—a collection of devices that will all be created when the batch is invoked. For example, in the standard DEVINFO, “generic” is a batch.
<code>block device-spec</code>	This defines one or more block devices.
<code>char device-spec</code>	This defines one or more character devices.

Here is a sample `device-spec`:

```
(std, 1) {
mem (kmem) : 1
null (public) : 3
core -> "/proc/kcore"
}
```

This example defines a group of devices called `std`, with major number 1. Running will create all the devices in the group; running, for example, would make just the one device `null`.

It is possible to specify, instead of just `std`, something like `std=foo`. In this case, the stuff on the right-hand side of the equals sign specifies a name from `/proc/devices`, and the major number will be retrieved from there if present. If an entry from `/proc/devices` is specified, the explicit major number may be omitted. In this case, if the number is not found in `/proc/devices`, attempts to create the device will be rejected.

Inside the braces is a list of specific devices. The name in parenthesis is the “class”; this is something specified in `MAKEDEV.cfg` that determines the ownership and permissions of the special file created. In the preceding example, the device `mem` was set to have the class `kmem`, but `null` was set to be `public`. Ordinarily, you’d define `public` to be mode 666 but `kmem` to be mode 660 and owned by group `kmem`. The number after the colon is the minor number for this particular device; for instance, 3 for `null`.

You may also specify a symbolic link with `->`. For instance, `core` was made a link to `/proc/kcore`. Note that names may contain any characters, but names that contain things other than alphanumerics, dash, and underscore should be put in double quotes.

An entire range of devices can be created. You may specify a range of numbers in brackets:

```
tty[1-8] (tty) : 1
```

This creates `tty1–tty8` with minor device numbers starting with 1. If you specify the range in hex (prefixed by `0x`), the device names will be created numbered in hex, as is normal for `ptys`. The range may appear inside the name string, but there may only be one range.

There is a special syntax for creating the entire banks of devices for a hard drive:

```
hd[a-d] 8/64
```

What this means is as follows: Create `hda`, and eight partitions on `hda` (`hda1` through `hda8`), starting with minor number 0. Then create `hdb`, and eight partitions, starting with minor number 64. Then `hdc`, and so on, with minor number $64 * 2 = 128$ —and so forth. These are automatically placed in the class `disk`. The necessary groups and batches are created so you can ask `MAKEDEV` to create `hd` or `hda` or `hda1` and expect it to do the correct thing.

Note that simple arithmetic is permitted for specifying the minor device number, as this often makes things much clearer and less likely to be accidentally broken.

Version 1.4, January 1995

environ

`environ`—User environment.

SYNOPSIS

```
extern char **environ;
```

DESCRIPTION

An array of strings called the `environment` is made available by `exec(2)` when a process begins. By convention, these strings have the form `name=val ue`. Common examples are

<code>USER</code>	The name of the logged-in user (used by some BSD-derived programs).
<code>LOGNAME</code>	The name of the logged-in user (used by some System-V derived programs).
<code>HOME</code>	A user's login directory, set by <code>login(1)</code> from the password file <code>passwd(5)</code> .
<code>LANG</code>	The name of a locale to use for locale categories when not overridden by <code>LC_ALL</code> or more specific environment variables.
<code>PATH</code>	The sequence of directory prefixes that <code>sh(1)</code> and many other programs apply in searching for a file known by an incomplete pathname. The prefixes are separated by <code>..</code>
<code>SHELL</code>	The filename of the user's login shell.
<code>TERM</code>	The terminal type for which output is to be prepared.

Further names maybe placed in the environment by the `export` command and `name=val ue` in `sh(1)` or by the `setenv` command if you use `csh(1)`. Arguments may also be placed in the environment at the point of an `exec(2)`.

It is risky practice to set `name=val ue` pairs that conflict with well-known shell variables. Setting these could cause surprising behavior in subshells or `system(3)` commands.

expire.ctl

`expire.ctl`—Control file for Usenet article expiration.

DESCRIPTION

The file `/news/lib/expire.ct1` is the default control file for the `expire(8)` program, which reads it at startup. Blank lines and lines beginning with a number sign (`#`) are ignored. All other lines should be in one of two formats.

The first format specifies how long to keep a record of fully expired articles. This is useful when a newsfeed intermittently offers older news that is not kept around very long. (The case of very old news is handled by the `-c` flag of `innd(8)`.) There should only be one line in this format, which looks like this:

```
/remember/:days
```

Where `days` is a floating-point number that specifies the upper limit to remember a Message-ID, even if the article has already expired. (It does not affect article expirations.)

Most of the lines in the file will consist of five colon-separated fields, as follows:

```
pattern:modflag:keep:default:purge
```

The `pattern` field is comma-separated set of single `wildmat(3)`-style patterns that specify the newsgroups to which the rest of the line applies. Because the file is interpreted in order, the most general patterns should be specified first, and the most specific patterns should be specified last.

The `modflag` field can be used to further limit newsgroups to which the line applies and should be chosen from the following set:

M	Only moderated groups
U	Only unmoderated groups
A	All groups

The next three fields are used to determine how long an article should be kept. Each field should be either a number of days (fractions such as `8.5` are allowed) or the word `never`. The most common use is to specify the default value for how long an article should be kept. The first and third fields—`keep` and `purge`—specify the boundaries within which an Expires header will be honored. They are ignored if an article has no Expires header. The fields are specified in the file as “lower-bound default upper-bound,” and they are explained in this order. Because most articles do not have explicit expiration dates, however, the second field tends to be the most important one.

The `keep` field specifies how many days an article should be kept before it will be removed. No article in the newsgroup will be removed if it has been filed for less than `keep` days, regardless of any expiration date. If this field is the word `never`, then an article cannot have been kept for enough days so it will never be expired.

The `default` field specifies how long to keep an article if no Expires header is present. If this field is the word `never`, then articles without explicit expiration dates will never be expired.

The `purge` field specifies the upper bound on how long an article can be kept. No article will be kept longer than the number of days specified by this field. All articles will be removed after they have been kept for `purge` days. If `purge` is the word `never`, then the article will never be deleted.

It is often useful to honor the expiration headers in articles, especially those in moderated groups. To do this, set `keep` to zero, `default` to whatever value you want, and `purge` to `never`. To ignore any Expires header, set all three fields to the same value.

There must be exactly one line with a `pattern` of `*` and a `modflag` of `A`; this matches all groups and is used to set the expiration default. It should be the first expiration line. For example:

```
## How long to keep expired history
/remember/:5
## Most things stay for two weeks
:A:14:14:14
## Believe expiration dates in moderated groups, up to six weeks
:M:1:30:42
## Keep local stuff for a long time
foo.*:A:30:30:30
```

exports

exports—NFS filesystems being exported.

SYNOPSIS

`/etc/exports`

DESCRIPTION

The file `/etc/exports` serves as the access control list for filesystems that can be exported to NFS clients. It is used by both the NFS mount daemon `mountd(8)` and the NFS file server daemon `nfsd(8)`.

The file format is similar to the SunOS `exports` file, except that several additional options are permitted. Each line contains a mount point and a list of machine or netgroup names allowed to mount the filesystem at that point. An optional parenthesized list of mount parameters may follow each machine name. Blank lines are ignored, and a `#` introduces a comment to the end of the line.

GENERAL OPTIONS

<code>secure</code>	This option requires that requests originate on an Internet port less than <code>IPPORT_RESERVED</code> (1024). This option is on by default. To turn it off, specify <code>insecure</code> .
<code>ro</code>	Allow only read-only requests on this NFS volume. The default is to allow write requests as well, which can also be made explicit by using the <code>rw</code> option.
<code>link_relative</code>	Convert absolute symbolic links (where the link contents start with a slash) into relative links by prepending the necessary number of <code>../s</code> to get from the directory containing the link to the root on the server. This has subtle, perhaps questionable, semantics when the file hierarchy is not mounted at its root.
<code>link_absolute</code>	Leave all symbolic links as they are. This is the default operation.

USER ID MAPPING

`nfsd` bases its access control to files on the server machine on the UID and GID provided in each NFS RPC request. The normal behavior a user would expect is that she can access her files on the server just as she would on a normal filesystem. This requires that the same UIDs and GIDs are used on the client and the server machine. This is not always true, nor is it always desirable.

Very often, it is not desirable that the root user on a client machine is also treated as root when accessing files on the NFS server. To this end, UID `0` is normally mapped to a different ID: the so-called anonymous or `nobody` UID. This mode of operation (called root squashing) is the default and can be turned off with `no_root_squash`.

By default, `nfsd` tries to obtain the anonymous UID and GID by looking up user `nobody` in the password file at startup time. If it isn't found, a UID and GID of `-2` (65534) is used. These values can also be overridden by the `anonuid` and `anongid` options.

In addition to this, `nfsd` lets you specify arbitrary UIDs and GIDs that should be mapped to user `nobody` as well. Finally, you can map all user requests to the anonymous UID by specifying the `all_squash` option.

For the benefit of installations where UIDs differ between different machines, `nfsd` provides a way to dynamically map server UIDs to client UIDs and vice versa. This is enabled with the `map` daemon option and uses the `UGID` RPC protocol. For this to work, you have to run the `ugidd(8)` mapping daemon on the client host.

Here's the complete list of mapping options:

<code>root_squash</code>	Map requests from UID/GID 0 to the anonymous UID/GID. Note that this does not apply to any other UIDs that might be equally sensitive, such as user <code>bin</code> .
<code>no_root_squash</code>	Turn off root squashing. This option is mainly useful for diskless clients.
<code>squash_uids</code> and <code>squash_gids</code>	This option specifies a list of UIDs or GIDs that should be subject to anonymous mapping. A valid list of IDs looks like this: <code>squash_uids=0-15,20,25-50</code> Usually, your squash lists will look a lot simpler, such as <code>squash_uids=0-100</code>
<code>all_squash</code>	Map all UIDs and GIDs to the anonymous user. Useful for NFS-exported public FTP directories, newspool directories, and so on. The opposite option is <code>no_all_squash</code> , which is the default setting.
<code>map_daemon</code>	This option turns on dynamic UID/GID mapping. Each UID in an NFS request will be translated to the equivalent server UID, and each UID in an NFS reply will be mapped the other way round. This option requires that <code>rpc.ugidd(8)</code> runs on the client host. The default setting is <code>map_identity</code> , which leaves all UIDs untouched. The normal squash options apply regardless of whether dynamic mapping is requested.
<code>anonuid</code> and <code>anongid</code>	These options explicitly set the UID and GID of the anonymous account. This option is primarily useful for PC/NFS clients, where you might want all requests appear to be from one user. As an example, consider the export entry for <code>/home/joe</code> in the section "Example," which maps all requests to UID 150 (which is supposedly that of user <code>joe</code>).

EXAMPLE

```
# sample /etc/exports file
/ master(rw) trusty(rw,no_root_squash)
/projects proj*.local.domain(rw)
/usr *.local.domain(ro) @trusted(rw)
/home/joe pc001(rw,all_squash,anonuid=150,anongid=100)
/pub (ro,insecure,all_squash)
```

The first line exports the entire filesystem to machines `master` and `trusty`. In addition to write access, all UID squashing is turned off for host `trusty`. The second and third entry show examples for wildcard hostnames and netgroups (this is the entry `@trusted`). The fourth line shows the entry for the PC/NFS client discussed previously. The last line exports the public FTP directory to every host in the world, executing all requests under the `nobody` account. The `insecure` option in this entry also allows clients with NFS implementations that don't use a reserved port for NFS.

CAVEATS

Unlike other NFS server implementations, this `nfsd` allows you to export both a directory and a subdirectory thereof to the same host, for instance `/usr` and `/usr/X11R6`. In this case, the mount options of the most specific entry apply. For instance, when a user on the client host accesses a file in `/usr/X11R6`, the mount options given in the `/usr/X11R6` entry apply. This is also true when the latter is a wildcard or netgroup entry.

FILES

<code>/etc/exports</code>	Configuration file for <code>nfsd(8)</code>
<code>/etc/passwd</code>	The password file

DIAGNOSTICS

An error parsing the file is reported using `syslogd(8)` as level `NOTICE` from a `DAEMON` whenever `nfsd(8)` or `mountd(8)` is started. Any unknown host is reported at that time, but often not all hosts are not yet known to `named(8)` at boot time, so as hosts are found, they are reported with the same `syslogd(8)` parameters.

fileystems

fileystems—Linux filesystem types: minix, ext, ext2, xia, msdos, umsdos, vfat, proc, nfs, iso9660, hpfs, sysv, smb, ncdfs.

DESCRIPTION

In the file `/proc/fileystems`, you can find which filesystems your kernel currently supports. (If you need a currently unsupported one, insert the corresponding module or recompile the kernel.)

Following is a description of the various filesystems.

minix	The filesystem used in the Minix operating system, the first to run under Linux. It has a number of shortcomings: a 64MB partition size limit, short filenames, a single time stamp, and so on. It remains useful for floppies and RAM disks.
ext	An elaborate extension of the <code>minix</code> filesystem. It has been completely superseded by the second version of the extended filesystem (<code>ext2</code>) and will eventually be removed from the kernel.
ext2	The high performance disk filesystem used by Linux for fixed disks as well as removable media. The second extended filesystem was designed as an extension of the extended filesystem (<code>ext</code>). <code>ext2</code> offers the best performance (in terms of speed and CPU usage) of the filesystems supported under Linux.
xiafs	Designed and implemented to be a stable, safe filesystem by extending the Minix filesystem code. It provides the basic, most requested features without undue complexity. The <code>xia</code> filesystem is no longer actively developed or maintained. It is used infrequently.
msdos	The filesystem used by DOS, Windows, and some OS/2 computers. <code>msdos</code> filenames can be no longer than an eight-character name followed by an optional period and three-character extension.
umsdos	An extended DOS filesystem used by Linux. It adds capability for long filenames, UID/GID, POSIX permissions, and special files (devices, named pipes, and so on) under the DOS filesystem, without sacrificing compatibility with DOS.
vfat	Extended DOS filesystem used by Microsoft Windows 95 and Windows NT. <code>vfat</code> adds capability for long filenames under the MS-DOS filesystem.
proc	A pseudo-filesystem that is used as an interface to kernel data structures rather than reading and interpreting <code>/dev/kmem</code> . In particular, its files do not take disk space. See <code>proc(5)</code> .
iso9660	A CD-ROM filesystem type conforming to the ISO 9660 standard.
High Sierra	Linux supports High Sierra, the precursor to the ISO 9660 standard for CD-ROM filesystems. It is automatically recognized within the <code>iso9660</code> filesystem support under Linux.
Rock Ridge	Linux also supports the System Use Sharing Protocol records specified by the Rock Ridge Interchange Protocol. They are used to further describe the files in the <code>iso9660</code> filesystem to a UNIX host and provides information such as long filenames, UID/GID, POSIX permissions, and devices. It is automatically recognized within the <code>iso9660</code> filesystem support under Linux.
hpfs	The High Performance Filesystem, used in OS/2. This filesystem is read-only under Linux due to the lack of available documentation.
sysv	An implementation of the SystemV/Coherent filesystem for Linux. It implements all Xenix FS, SystemV/386 FS, and Coherent FS.
nfs	The network filesystem used to access disks located on remote computers.

smb	A network filesystem that supports the SMB protocol, used by Windows for Workgroups, Windows NT, and LAN Manager. To use <code>smb</code> , you need a special mount program, which can be found in the <code>ksmbfs</code> package at ftp://sunsite.unc.edu/pub/Linux/system/Filesystems/smbfs .
ncpfs	A network filesystem that supports the NCP protocol, used by Novell NetWare. To use <code>ncpfs</code> , you need special programs found at ftp://linux01.gwdg.de/pub/ncpfs .

fstab

`fstab`—Static information about the filesystems.

SYNOPSIS

```
#include <fstab.h>
```

DESCRIPTION

The file `fstab` contains descriptive information about the various filesystems. `fstab` is only read by programs and not written; it is the duty of the system administrator to properly create and maintain this file. Each filesystem is described on a separate line; fields on each line are separated by tabs or spaces. The order of records in `fstab` is important because `fsck(8)`, `mount(8)`, and `umount(8)` sequentially iterate through `fstab` doing their thing.

The first field (`fs_spec`) describes the block special device or remote filesystem to be mounted.

The second field (`fs_file`) describes the mount point for the filesystem. For swap partitions, this field should be specified as `none`.

The third field (`fs_vfstype`) describes the type of the filesystem. The system currently supports three types of filesystems:

<code>minix</code>	A local filesystem, supporting filenames of length 14 or 30 characters.
<code>ext</code>	A local filesystem with longer filenames and larger inodes. This filesystem has been replaced by the <code>ext2</code> filesystem and should no longer be used.
<code>ext2</code>	A local filesystem with longer filenames, larger inodes, and a lot of other features.
<code>xiafs</code>	A local filesystem with longer filenames, larger inodes, and a lot of other features.
<code>msdos</code>	A local filesystem for MS-DOS partitions.
<code>hpfs</code>	A local filesystem for HPFS partitions.
<code>iso9660</code>	A local filesystem used for CD-ROM drives.
<code>nfs</code>	A filesystem for mounting partitions from remote systems.
<code>swap</code>	A disk partition to be used for swapping.

If `vs_fstype` is specified as `ignore`, the entry is ignored. This is useful to show disk partitions that are currently unused.

The fourth field (`fs_mntops`) describes the mount options associated with the filesystem.

It is formatted as a comma-separated list of options. It contains at least the type of mount plus any additional options appropriate to the filesystem type. For documentation on the available options for non-NFS file systems, see `mount(8)`. For documentation on all NFS-specific options, take a look at `nfs(5)`. Common for all types of filesystems are the options `noauto` (do not mount when `mount -a` is given, such as at boot time) and `user` (allow a user to mount). For more details, see `mount(8)`.

The fifth field (`fs_freq`) is used for these filesystems by the `dump(8)` command to determine which filesystems need to be dumped. If the fifth field is not present, a value of zero is returned and `dump` will assume that the filesystem does not need to be dumped.

The sixth field (`fs_passno`) is used by the `fsck(8)` program to determine the order in which filesystem checks are done at reboot time. The root filesystem should be specified with a `fs_passno` of 1, and other filesystems should have a `fs_passno` of 2. Filesystems within a drive will be checked sequentially, but filesystems on different drives will be checked at the same time to utilize parallelism available in the hardware. If the sixth field is not present or zero, a value of zero is returned and `fsck` will assume that the filesystem does not need to be checked.

The proper way to read records from `fstab` is to use the routine `getmntent(3)`.

HISTORY

The `fstab` file format appeared in 4.0 BSD.

Linux 0.99, 27 November 1993

groff_font

`groff_font`—Format of `groff` device and font description files.

DESCRIPTION

The `groff_font` format is roughly a superset of the `ditroff` font format. Unlike the `ditroff` font format, there is no associated binary format. The font files for device `name` are stored in a directory `devname`. There are two types of file: a device description file called `DESC` and for each font `F`, a font file called `F`. These are text files; there is no associated binary format.

DESC FILE FORMAT

The `DESC` file can contain the following types of lines:

<code>res n</code>	There are <code>n</code> machine units per inch.
<code>hor n</code>	The horizontal resolution is <code>n</code> machine units.
<code>vert n</code>	The vertical resolution is <code>n</code> machine units.
<code>sizescale n</code>	The scale factor for point sizes. By default, this has a value of 1. One scaled point is equal to one point/ <code>n</code> . The arguments to the <code>unitwidth</code> and <code>sizes</code> commands are given in scaled points.
<code>unitwidth n</code>	Quantities in the font files are given in machine units for fonts whose point size is <code>n</code> scaled points.
<code>tcommand</code>	This means that the postprocessor can handle the <code>t</code> and <code>u</code> output commands.
<code>sizes s1 s2 ... sn</code>	This means that the device has fonts at <code>s1</code> , <code>s2</code> , ..., <code>sn</code> scaled points. The list of sizes must be terminated by a <code>0</code> . Each <code>si</code> can also be a range of sizes <code>m-n</code> . The list can extend over more than one line.
<code>styles S1 S2 ... Sm</code>	The first <code>m</code> font positions will be associated with styles <code>S1</code> ... <code>Sm</code> .
<code>fonts n F1 F2 F3 ... Fn</code>	Fonts <code>F1</code> ... <code>Fn</code> will be mounted in the font positions <code>m+1</code> , ..., <code>m+n</code> where <code>m</code> is the number of styles. This command may extend over more than one line. A font name of <code>0</code> will cause no font to be mounted on the corresponding font position.

<code>family fam</code>	The default font family is <code>fam</code> .
<code>charset</code>	This line and everything following in the file are ignored. It is allowed for the sake of backwards compatibility.

The `res`, `unitwidth`, `fonts`, and `sizes` lines are compulsory. Other commands are ignored by `troff` but may be used by postprocessors to store arbitrary information about the device in the `DESC` file.

FONT FILE FORMAT

A font file has two sections. The first section is a sequence of lines, each containing a sequence of blank delimited words; the first word in the line is a key, and subsequent words give a value for that key.

<code>name F</code>	The name of the font is <code>F</code> .
<code>spacewidth n</code>	The normal width of a space is <code>n</code> .
<code>slant n</code>	The characters of the font have a slant of <code>n</code> degrees. (Positive means forward.)
<code>ligatures lig1 lig2 ... lig_n [0]</code>	Characters <code>lig1</code> , <code>lig2</code> , ..., <code>lig_n</code> are ligatures; possible ligatures are <code>ff</code> , <code>fi</code> , <code>fl</code> , and <code>ffl</code> . For backwards compatibility, the list of ligatures may be terminated with a <code>0</code> . The list of ligatures may not extend over more than one line.
<code>special</code>	The font is <code>special</code> ; this means that when a character is requested that is not present in the current font, it will be searched for in any special fonts that are mounted.

Other commands are ignored by `troff` but may be used by postprocessors to store arbitrary information about the font in the font file.

The first section can contain comments, which start with the `#` character and extend to the end of a line.

The second section contains one or two subsections. It must contain a `charset` subsection and it may also contain a `kernpairs` subsection. These subsections can appear in any order. Each subsection starts with a word on a line by itself.

The word `charset` starts the `charset` subsection. The `charset` line is followed by a sequence of lines. Each line gives information for one character. A line comprises a number of fields separated by blanks or tabs. The format is

```
name metrics type code comment
```

`name` identifies the character: if `name` is a single character `c`, it corresponds to the `groff` input character `c`; if it is of the form `\c` where `c` is a single character, then it corresponds to the `groff` input character `nc`; otherwise, it corresponds to the `groff` input character `\[name]` (if it is exactly two characters `xx`, it can be entered as `\(xx)`). `groff` supports eight-bit characters; however, some utilities have difficulties with eight-bit characters. For this reason, there is a convention that the name `charn` is equivalent to the single character whose code is `n`. For example, `char163` is equivalent to the character with code 163, which is the pounds sterling sign in ISO Latin-1. The name `—` is special and indicates that the character is unnamed; such characters can only be used by means of the `\N` escape sequence in `troff`.

The `type` field gives the character type:

1	The character has an descender, such as <code>p</code> .
2	The character has an ascender, such as <code>b</code> .
3	The character has both an ascender and a descender, such as <code>(</code> .

The `code` field gives the code that the postprocessor uses to print the character. The character can also be input to `groff` using this code by means of the `\N` escape sequence. The code can be any integer. If it starts with a `0`, it will be interpreted as octal; if it starts with `0x` or `0X`, it will be interpreted as hexadecimal.

Anything on the line after the code field will be ignored.

The `metrics` field has the form:

```
width[,height[,depth[,italic_correction[,left_italic_correction
↳[,subscript_correction]]]]]
```

There must not be any spaces between these subfields. Missing subfields are assumed to be `0`. The subfields are all decimal integers. Because there is no associated binary format, these values are not required to fit into a variable of type `char` as they

are in `ditroff`. The `width` subfields gives the width of the character. The `height` subfield gives the height of the character (upwards is positive); if a character does not extend above the baseline, it should be given a zero height, rather than a negative height. The `depth` subfield gives the depth of the character, that is, the distance below the lowest point below the baseline to which the character extends (downwards is positive); if a character does not extend below above the baseline, it should be given a zero depth, rather than a negative depth. The `italic_correction` subfield gives the amount of space that should be added after the character when it is immediately to be followed by a character from a roman font. The `left_italic_correction` subfield gives the amount of space that should be added before the character when it is immediately to be preceded by a character from a roman font. The `subscript_correction` gives the amount of space that should be added after a character before adding a subscript. This should be less than the `italic_correction`.

A line in the `charset` section can also have the format

```
name "
```

This indicates that `name` is just another name for the character mentioned in the preceding line.

The word `kernpairs` starts the `kernpairs` section. This contains a sequence of lines of the form:

```
c1 c2 n
```

This means that when character `c1` appears next to character `c2`, the space between them should be increased by `n`. Most entries in `kernpairs` section will have a negative value for `n`.

FILES

```
/usr/lib/groff/font/dev name/DESC    Device description file for device name.
/usr/lib/groff/font/devname/F        Font file for font F of device name.
```

Groff Version 1.09, 14 February 1994

groff_out

`groff_out`—`groff` intermediate output format.

DESCRIPTION

This manual page describes the format output by GNU `troff`. The output format used by GNU `troff` is very similar to that used by UNIX device-independent `troff`. Only the differences are documented here.

The argument to the `s` command is in scaled points (units of points/`n`, where `n` is the argument to the `sizescale` command in the `DESC` file.) The argument to the `x Height` command is also in scaled points.

The first three output commands are guaranteed to be

```
x T device
x res n h v
x init
```

If the `t` command line is present in the `DESC` file, `troff` will use the following two commands:

```
txxx          xxx is any sequence of characters terminated by a space or a newline; the first
              character should be printed at the current position, the current horizontal position
              should be increased by the width of the first character, and so on for each character.
              The width of the character is that given in the font file, appropriately scaled for the
              current point size and rounded so that it is a multiple of the horizontal resolution.
              Special characters cannot be printed using this command.
```

`unxxx` This is same as the `t` command except that after printing each character, the current horizontal position is increased by the sum of the width of that character and `n`.

Note that single characters can have the eighth bit set, as can the names of fonts and special characters.

The names of characters and fonts can be of arbitrary length; drivers should not assume that they will be only two characters long.

When a character is to be printed, that character will always be in the current font. Unlike device-independent `troff`, it is not necessary for drivers to search special fonts to find a character.

The `D` drawing command has been extended. These extensions will not be used by GNU `pic` if the `-n` option is given.

<code>Df n\n</code>	Set the shade of gray to be used for filling solid objects to <code>n</code> ; <code>n</code> must be an integer between 0 and 1000, where 0 corresponds to solid white and 1000 to solid black and values in between correspond to intermediate shades of gray. This applies only to solid circles, solid ellipses, and solid polygons. By default, a level of 1000 will be used. Whatever color a solid object has, it should completely obscure everything beneath it. A value greater than 1000 or less than 0 can also be used: This means fill with the shade of gray that is currently being used for lines and text. Normally, this will be black, but some drivers may provide a way of changing this.
<code>DC d\n</code>	Draw a solid circle with a diameter of <code>d</code> with the leftmost point at the current position.
<code>DE dx dy\n</code>	Draw a solid ellipse with a horizontal diameter of <code>dx</code> and a vertical diameter of <code>dy</code> with the leftmost point at the current position.
<code>Dp dx1 dy1 dx2 dy2 ... dxn dyn\n</code>	Draw a polygon with, for $i = 1, \dots, n+1$, the i th vertex at the current position + $\sum_{j=1}^{i-1} (dx_j, dy_j)$. At the moment, GNU <code>pic</code> only uses this command to generate triangles and rectangles.
<code>DP dx1 dy1 dx2 dy2 ... dxn dyn\n</code>	Like <code>Dp</code> , but draw a solid rather than outlined polygon.
<code>Dt n\n</code>	Set the current line thickness to <code>n</code> machine units. Traditionally, UNIX <code>troff</code> drivers use a line thickness proportional to the current point size; drivers should continue to do this if no <code>Dt</code> command has been given or if a <code>Dt</code> command has been given with a negative value of <code>n</code> . A zero value of <code>n</code> selects the smallest available line thickness.

A difficulty arises in how the current position should be changed after the execution of these commands. This is not of great importance because the code generated by GNU `pic` does not depend on this. Given a drawing command of the form

```
\Dc x1 y1 x2 y2 ... xn yn
```

where `c` is not one of `c`, `e`, `l`, `a`, or `~`, UNIX `troff` will treat each of the x_i as a horizontal quantity and each of the y_i as a vertical quantity and will assume that the width of the drawn object is $\sum_{i=1}^n x_i$ and that the height is $\sum_{i=1}^n y_i$. (The assumption about the height can be seen by examining the `st` and `sb` registers after using such a `D` command in a `\w` escape sequence.) This rule also holds for all the original drawing commands with the exception of `De`. For the sake of compatibility, GNU `troff` also follows this rule, even though it produces an ugly result in the case of the `Df`, `Dt`, and, to a lesser extent, `DE` commands. Thus after executing a `D` command of the form

```
Dc x1 y1 x2 y2 ... xn yn\n
```

the current position should be increased by $(\sum_{i=1}^n x_i; \sum_{i=1}^n y_i)$.

A continuation convention permits the argument to the `x X` command to contain newlines: when outputting the argument to the `x X` command, GNU `troff` will follow each newline in the argument with a `+` character (as usual, it will terminate the entire argument with a newline); thus if the line after the line containing the `x X` command starts with `+`, then the newline ending the line containing the `x X` command should be treated as part of the argument to the `x X` command, the `+` should be ignored, and the part of the line following the `+` should be treated like the part of the line following the `x X` command.

group

group—User group file.

DESCRIPTION

`/etc/group` is an ASCII file that defines the groups to which users belong. There is one entry per line, and each line has the format

```
group_name:passwd:GID:user_list
```

The field descriptions are

group_name	The name of the group.
passwd	The (encrypted) group password. If this field is empty, no password is needed.
GID	The numerical group ID.
user_list	All the group member's usernames, separated by commas.

FILES

`/etc/group`

Linux, 29 December 1992

history

history—Record of current and recently expired Usenet articles.

DESCRIPTION

The file `/news/lib/history` keeps a record of all articles currently stored in the news system, as well as those that have been received but since expired.

The file consists of text lines. Each line corresponds to one article. The file is normally kept sorted in the order in which articles are received, although this is not a requirement. `innd(8)` appends a new line each time it files an article, and `expire(8)` builds a new version of the file by removing old articles and purging old entries.

Each line consists of two or three fields separated by a tab, shown below as `\t`:

```
<Message-ID>\t date
<Message-ID>\t date \t files
```

The `Message-ID` field is the value of the article's Message-ID header, including the angle brackets.

The `date` field consists of three subfields separated by a tilde. All subfields are the text representation of the number of seconds since the epoch—a `time_t`; see `gettimeofday(2)`. The first subfield is the article's arrival date. If copies of the article are still present, then the second subfield is either the value of the article's Expires header or a hyphen if no expiration date was specified. If an article has been expired, the second subfield will be a hyphen. The third subfield is the value of the article's Date header, recording when the article was posted.

The `files` field is a set of entries separated by one or more spaces. Each entry consists of the name of the newsgroup, a slash, and the article number. This field is empty if the article has been expired.

For example, an article cross-posted to `comp.sources.unix` and `comp.sources.d` that was posted on February 10, 1991, (and received three minutes later) with an expiration date of May 5, 1991, could have a history line (broken into two lines for display) like the following:

```
<312@litchi.foo.com> \t 666162000`673329600`666162180
\t comp.sources.unix/1104 comp.sources.d/7056
```

In addition to the text file, there is a `dbz(3z)` database associated with the file that uses the Message-ID field as a key to determine the offset in the text file where the associated line begins. For historical reasons, the key includes the trailing `\0` byte (which is not stored in the text file).

HISTORY

Written by Rich Salz (`rsalz@uunet.uu.net`) for InterNetNews.

hosts.nntp, hosts.nntp.nolimit

`hosts.nntp`, `hosts.nntp.nolimit`—List of hosts that feed NNTP news.

DESCRIPTION

The file `/news/lib/hosts.nntp` is read by `innd(8)` to get the list of hosts that feed the local site Usenet news using the NNTP protocol. The server reads this file at startup or when directed to by `ctlinnd(8)`. When a hosts connects to the NNTP port of the system on which `innd` is running, the server will do a check to see if their Internet address is the same as one of the hosts named in this file. If the host is not mentioned, then `innd` will spawn an `nnrpd(8)` to process the connection, with the accepted connection on standard input and standard output.

Comments begin with a number sign (`#`) and continue through the end of the line. Blank lines and comments are also ignored. All other lines should consist of two or three fields separated by a colon.

The first field should be either an Internet address in dotted-quad format or an address that can be parsed by `gethostbyname(3)`. If a host's entry has multiple addresses, all of them will be added to the access list. The second field, which may be blank, is the password the foreign host is required to use when first connecting. The third field, which may be omitted, is a list of newsgroups to which the host may post articles. This list is parsed as a `newsfeeds(5)` subscription list; groups not in the list are ignored.

Because `innd` is usually started at system boot time, the local nameserver may not be fully operational when `innd` parses this file. As a work-around, a `ctlinnd reload` command can be performed after a delay of an hour or so. It is also possible to provide both a host's name and its dotted-quad address in the file.

For example:

```
## FOO has a password, UUNET doesn't.
## UUNET cannot post to local groups.
## These are comment lines.
news.foo.com:magic
uunet.uu.net::!foo.*
```

If the file contains passwords, it should not be world-readable. The file `/news/lib/hosts.nntp.nolimit`, if it exists, is read whenever the `hosts.nntp` file is read. It has the same format, although only the first field is used. Any host mentioned in this file is not subject to the incoming connections limit specified by `innd's -c` flag. This can be used to allow local hosts or time-sensitive peers to connect regardless of the local conditions.

HISTORY

Written by Rich Salz (rsalz@uunet.uu.net) for InterNetNews.

hosts_access

hosts_access—Format of host access control files.

DESCRIPTION

This manual page describes a simple access control language that is based on client (hostname/address, username) and server (process name) patterns. Examples are given at the end. The impatient reader can skip to the “Examples” section for a quick introduction.

In the following text, `daemon` is the process name of a network daemon process, and `client` is the name or address of a host requesting service. Network daemon process names are specified in the `inetd` configuration file.

ACCESS CONTROL FILES

The access control software consults two files. The search stops at the first match:

Access will be granted when a (`daemon,client`) pair matches an entry in the `/etc/hosts.allow` file.

Otherwise, access will be denied when a (`daemon,client`) pair matches an entry in the `/etc/hosts.deny` file.

Otherwise, access will be granted.

A non-existing access control file is treated as if it were an empty file. Thus, access control can be turned off by providing no access control files.

ACCESS CONTROL RULES

Each access control file consists of zero or more lines of text. These lines are processed in order of appearance. The search terminates when a match is found.

A newline character is ignored when it is preceded by a backslash character.

Blank lines or lines that begin with a `#` character are ignored.

All other lines should satisfy the following format, things between `[]` being optional:

```
daemon_list : client_list [ : shell_command ]
```

`daemon_list` is a list of one or more daemon process names (`argv[0]` values) or wildcards.

`client_list` is a list of one or more hostnames, host addresses, patterns, or wildcards that will be matched against the remote hostname or address.

List elements should be separated by blanks or commas.

With the exception of NIS (YP) netgroup lookups, all access control checks are case insensitive.

PATTERNS

The access control language implements the following patterns:

A string that begins with a `.` character: A client name or address is matched if its last components match the specified pattern. For example, the pattern `.tue.nl` matches the hostname `wzv.win.tue.nl`.

A string that ends with a `.` character: A client name or address is matched if its first fields match the given string. For example, the pattern `131.155.` matches the address of (almost) every host on the Eindhoven University network (`131.155.x.x`).

A string that begins with a @ character is treated as a netgroup name: Netgroups are usually supported on systems with NIS (formerly YP) databases. A client hostname is matched if it is a (host) member of the specified netgroup.

An expression of the form `n.n.n.n/m.m.m.m` is interpreted as a `net/mask` pair. A client address is matched if `net` is equal to the bitwise AND of the address and the `mask`. For example, the `net/mask` pattern `131.155.72.0/255.255.254.0` matches every address in the range `131.155.72.0` through `131.155.73.255`.

WILDCARDS

The access control language supports explicit wildcards:

ALL	If this token appears in a daemon list, it matches all network daemon process names. If the ALL token appears in a client list, it matches all client names and addresses.
LOCAL	Matches any string that does not contain a dot character. Typical use is in client lists.
UNKNOWN	Matches any host whose name or address are unknown. Should be used with care: Hostnames may be unavailable due to temporary nameserver problems. A network address will be unavailable when the software cannot figure out what type of network it is talking to.
KNOWN	Matches any host whose name and address are known. Should be used with care: Hostnames may be unavailable due to temporary nameserver problems. A network address will be unavailable when the software cannot figure out what type of network it is talking to.
FAIL	Like the ALL wildcard but causes the software to pretend that the scan of the current access control table fails. FAIL is being phased out; it will become an undocumented feature. The EXCEPT operator is a much cleaner alternative.

OPERATORS

EXCEPT	Intended use is of the form: <code>list_1 EXCEPT list_2</code> ; this construct matches anything that matches <code>list_1</code> unless it matches <code>list_2</code> . This construct can be used in daemon lists and in client lists. The EXCEPT operator can be nested: If the control language would permit the use of parentheses, a <code>EXCEPT b EXCEPT c</code> would parse as <code>(a EXCEPT (b EXCEPT c))</code> .
--------	--

SHELL COMMANDS

If the first-matched access control rule contains a shell command, that command is subjected to the following substitutions:

%a	Expands to the remote host address.
%c	Expands to client information: <code>user@host</code> , <code>user@address</code> , a hostname, or just an address, depending on how much information is available.
%h	Expands to the remote hostname (or address, if the hostname is unavailable).
%d	Expands to the daemon process name (<code>argv[0]</code> value).
%p	Expands to the daemon process ID.
%u	Expands to the remote username (or <code>unknown</code>).
%%	Expands to a single % character.

Characters in % expansions that may confuse the shell are replaced by underscores. The result is executed by a `/bin/sh` child process with standard input, output, and error connected to `/dev/null`. Specify an & at the end of the command if you do not want to wait until it has completed.

Shell commands should not rely on the `PATH` setting of the `inetd`. Instead, they should use absolute pathnames, or they should begin with an explicit `PATH=whatever` statement.

REMOTE USERNAME LOOKUP

When the client host supports the RFC 931 protocol or one of its descendants (`TAP`, `IDENT`) the wrapper programs can retrieve additional information about the owner of a connection. When available, remote username information is logged together with the client hostname and can be used to match patterns like

```
daemon_list : ... user_pattern@host_pattern ...
```

The daemon wrappers can be configured at compile time to perform rule-driven username lookups (default) or to always interrogate the client host. In the case of rule-driven username lookups, the preceding rule would cause username lookup only when both the `daemon_list` and the `host_pattern` match.

A user pattern has the same syntax as a daemon process name, hostname, or host address pattern, so the same wildcards and so on apply (but `netgroup` membership of users is not supported). One should not get carried away with username lookups, however.

The remote username information cannot be trusted when it is needed most—that is, when the remote system has been compromised. In general, `ALL` and `(UN)KNOWN` are the only username patterns that make sense.

Username lookups are possible only with TCP-based services and only when the client host runs a suitable daemon; in all other cases the result is `unknown`.

A well-known UNIX kernel bug may cause loss of service when username lookups are blocked by a firewall. The wrapper `README` document describes a procedure to find out if your kernel has this bug.

Username lookups cause noticeable delays for PC users. The default time-out for username lookups is ten seconds: too short to cope with slow networks but long enough to irritate PC users.

Selective username lookups can alleviate the last problem. For example, a rule like

```
daemon_list : @pcnetgroup ALL@ALL
```

would match members of the `pcnetgroup` without doing username lookups but would perform username lookups with all other systems.

EXAMPLES

The language is flexible enough that different types of access control policy can be expressed with a minimum of fuss. Although the language uses two access control tables, the most common policies can be implemented with one of the tables being trivial or even empty.

When reading the following examples, it is important to realize that the `allow` table is scanned before the `deny` table, that the search terminates when a match is found, and that access is granted when no match is found at all.

The examples use host and domain names. They can be improved by including address or network/netmask information to reduce the impact of temporary nameserver lookup failures.

MOSTLY CLOSED

In this case, access is denied by default. Only explicitly authorized hosts are permitted access.

The default policy (no access) is implemented with a trivial deny file:

```
/etc/hosts.deny:
```

```
ALL: ALL
```

This denies all service to all hosts, unless they are permitted access by entries in the `allow` file.

The explicitly authorized hosts are listed in the `allow` file:

```
/etc/hosts.allow:
```

```
ALL: LOCAL @some_netgroup
```

```
ALL: .foobar.edu EXCEPT terminalserver.foobar.edu
```

The first rule permits access to all services from hosts in the local domain (no `.` in the hostname) and from members of the `some_netgroup` `netgroup`. The second rule permits access to all services from all hosts in the `.foobar.edu` domain, with the exception of `terminalserver.foobar.edu`.

MOSTLY OPEN

Here, access is granted by default; only explicitly specified hosts are refused service.

The default policy (access granted) makes the allow file redundant so that it can be omitted. The explicitly non-authorized hosts are listed in the deny file:

```
/etc/hosts.deny:
ALL: some.host.name, .some.domain
ALL EXCEPT in.fingerd: other.host.name, .other.domain
```

The first rule denies some hosts all services; the second rule still permits finger requests from other hosts.

BOOBY TRAPS

The next example permits `tftp` requests from hosts in the local domain. Requests from any other hosts are denied. Instead of the requested file, a finger probe is sent to the offending host. The result is mailed to the superuser.

```
/etc/hosts.allow:
in.tftpd: LOCAL, .my.domain
/etc/hosts.deny:
in.tftpd: ALL: (/some/where/safe_finger -l @%h | \
/usr/ucb/mail -s %d-%h root) &
```

The `safe_finger` command comes with the `tcpd` wrapper and should be installed in a suitable place. It limits possible damage from data sent by the remote finger server. It gives better protection than the standard `finger` command.

The expansion of the `%h` (remote host) and `%d` (service name) sequences is described in the section on shell commands.

Warning: Do not booby-trap your finger daemon, unless you are prepared for infinite finger loops.

On network firewall systems, this trick can be carried even further. The typical network firewall only provides a limited set of services to the outer world. All other services can be “bugged” just like the preceding `tftp` example. The result is an excellent early-warning system.

DIAGNOSTICS

An error is reported when a syntax error is found in a host access control rule, when the length of an access control rule exceeds the capacity of an internal buffer, when an access control rule is not terminated by a newline character, when the result of `%<character>` expansion would overflow an internal buffer, and when a system call fails that shouldn't. All problems are reported via the `syslog` daemon.

FILES

```
/etc/hosts.allow, (daemon,client) pairs that are granted access.
/etc/hosts.deny, (daemon,client) pairs that are denied access.
```

SEE ALSO

`tcpd(8)`, TCP/IP daemon wrapper program

BUGS

If a nameserver lookup times out, the hostname will not be available to the access control software, even though the host is registered.

Domain nameserver lookups are case insensitive; NIS (formerly YP) netgroup lookups are case sensitive.

hosts_options

hosts_options—Host access control language extensions.

DESCRIPTION

This document describes optional extensions to the language described in the `hosts_access(5)` document. The extensions are enabled at program build time by editing the makefile.

The extensible language uses the following format:

```
daemon_list : client_list : option : option ...
```

The first two fields are described in the `hosts_access(5)` manual page. The remainder of the rules is a list of zero or more options. Any `:` characters within options should be protected with a backslash.

An option is of the form `keyword` or `keyword = value`. Options are processed in the specified order. With some options, the value is subjected to `%<character>` substitutions.

OPTIONS

```
severity = mail.info
```

Change the severity level at which the event will be logged. Facility names (such as `mail`) are optional and are not supported on systems with older `syslog` implementations. The severity option can be used to emphasize or to completely ignore specific events.

```
allow (deny)
```

Grant (`deny`) service, even when the matched rule was found in the `hosts.deny` (`hosts.allow`) file. These options must appear at the end of a rule.

With the `allow` and `deny` keywords, it is possible to keep all access control rules within a single file—for example, in the `hosts.allow` file:

```
ALL: .friendly.domain: allow
ALL: ALL: deny
```

This permits access from specific hosts only. On the other hand,

```
ALL: .trouble.makers: deny
ALL: ALL: allow
```

This permits access from all hosts except a few troublemakers.

```
twist = shell_command
```

Replace the current process by an instance of the specified shell command, after performing the `%<character>` expansions described in the `hosts_access(5)` manual page. `stdin`, `stdout`, and `stderr` are connected to the remote client process. This option must appear at the end of a rule. Examples:

```
in.ftpd : ... : twist = /bin/echo 421
```

Some bounce message sends a customized bounce message to the remote client instead of running the real FTP daemon.

```
in.telnetd : ... : twist = PATH=/some/other; exec in.telnetd
```

Runs `/some/other/in.telnetd` without polluting its command-line array or its process environment.

Warning: In case of UDP services, do not twist into commands that use the standard I/O or the `read(2)/write(2)` routines to communicate with the client process; UDP requires other I/O primitives.

```
spawn = shell_command
```

Execute the shell command in a child process, after performing the `%<character>` expansions described in the `hosts_access(5)` manual page. The command

```
spawn = (/some/where/safe_finger -l @%h | /usr/ucb/mail root) &
```

```
umask = 022
```

```
keepalive
```

```
linger = number_of_seconds
```

```
nice = niceval
```

```
nice (no argument)
```

```
user = nobody
```

```
group = tty
```

```
setenv = name value
```

is executed with `stdin`, `stdout`, and `stderr` connected to the null device so that it won't mess up the conversation with the remote host. Example: Executes, in a background child process, the shell command `safe_finger -l @%h | mail root` after replacing `%h` by the name or address of the remote host.

The example uses the `safe_finger` command instead of the regular `finger` command to limit possible damage from data sent by the finger server. The `safe_finger` command is part of the `daemon wrapper` package; it is a wrapper around the regular `finger` command that filters the data sent by the remote host.

Like the `umask` command that is built into the shell. An `umask` of `022` prevents the creation of files with group and world write permission. The `umask` argument should be an octal number.

Causes the server to periodically send a message to the client. The connection is considered broken when the client does not respond. The `keepalive` option can be useful when users turn off their machine while it is still connected to a server. The `keepalive` option is not useful for datagram (UDP) services.

Specifies how long the kernel will try to deliver not-yet delivered data after the server process closes a connection.

Change the nice value of the process (default 10). Specify a positive value to spend more CPU resources on other processes.

Assume the privileges of the `nobody` account. This is useful with `inetd` implementations that run all services with root privilege. It is good practice to run services such as `finger` at a reduced privilege level.

Assume the privileges of the `tty` group. This is useful mostly in combination with the `user` option. In order to switch both user and group IDs, switch group ID before switching user ID.

Place a `(name, value)` pair into the process environment. The `value` is subjected to `%<character>` expansions and may contain whitespace (but leading and trailing blanks are stripped off).

Warning: Many network daemons reset their environment before spawning a login or shell process.

rfc931 = timeout_in_seconds

rfc931 (no argument)

Look up the remote user name with the RFC 931 (*ident* and *so on*) protocol. This option is silently ignored in case of services based on transports other than TCP. It requires that the client system runs an RFC 931 (*ident* and *so on*) compliant daemon and may cause noticeable delays with connections from non-UNIX hosts. The time-out period is optional. If no time-out is specified, a default value is taken.

DIAGNOSTICS

When a syntax error is found in an access control rule, the error is reported to the `syslog` daemon; further options will be ignored, and service is denied.

inittab

`inittab`—Format of the `inittab` file used by the SysV-compatible `init` process.

DESCRIPTION

The `inittab` file describes which processes are started at bootup and during normal operation (such as `/etc/rc`, `gettys`). `init` distinguishes multiple run levels, of which each can have its own set of processes that are started. Valid run levels are 0–6 and A, B, and C for ondemand entries. An entry in the `inittab` file has the following format:

```
id:run levels:action:process
```

Lines beginning with `#` are ignored.

<code>id</code>	A unique two-character-sequence which identifies an entry in <code>inittab</code> . Note: For <code>gettys</code> or other login processes, the <code>id</code> field should be the <code>tty</code> suffix of the corresponding <code>tty</code> , such as <code>1</code> for <code>tty1</code> . Otherwise, the login accounting will not work correctly. This is a bug in login and will be fixed.
<code>run levels</code>	Describes in which run levels the specified action should be taken.
<code>action</code>	Describes which action should be taken.
<code>process</code>	Specifies the process to be executed. If the process field starts with a <code>+</code> character, <code>init</code> will not do <code>utmp</code> and <code>wtmp</code> accounting for that process. This is needed for <code>gettys</code> that insist on doing their own <code>utmp/wtmp</code> housekeeping. This is also a historic bug.

Valid actions are

<code>respawn</code>	The process will be restarted whenever it terminates (such as <code>getty</code>).
<code>wait</code>	The process will be started once when the specified run level is entered and <code>init</code> will wait for its termination.
<code>once</code>	The process will be executed once when the specified run level is entered.
<code>boot</code>	The process will be executed during system boot. The run level field is ignored.

<code>bootwait</code>	The process will be executed during system boot while <code>init</code> waits for its termination (such as <code>/etc/rc</code>). The <code>runlevel</code> field is ignored.
<code>off</code>	This does nothing.
<code>ondemand</code>	A process marked with <code>ondemand</code> will be executed whenever the specified <code>ondemand</code> run level is called. However, no <code>runlevel</code> change will occur.
<code>initdefault</code>	An <code>initdefault</code> -entry specifies the run level that should be entered after system boot. If none exists, <code>init</code> will ask for a <code>runlevel</code> on the console.
<code>sysinit</code>	The process will be executed during system boot. It will be executed before any <code>boot</code> or <code>bootwait</code> entries.
<code>powerwait</code>	The process will be executed when <code>init</code> receives the <code>SIGPWR</code> signal, indicating that there is something wrong with the power. <code>init</code> will wait for the process to finish before continuing.
<code>powerfail</code>	As <code>powerwait</code> but <code>init</code> will not wait for the processes completion.
<code>powerokwait</code>	The process will be executed when <code>init</code> receives the <code>SIGPWR</code> signal, provided there is a file called <code>/etc/powerstatus</code> containing the word <code>OK</code> . This means that the power has come back again.
<code>ctrlaltdel</code>	The process will be executed when <code>init</code> receives the <code>SIGINT</code> signal. This means that someone on the system console pressed the <code>Ctrl+Alt+Del</code> key combination. Typically, one wants to execute some sort of shutdown either to get into single-user level or to reboot the machine.

The `runlevel` field may contain multiple characters for different run levels, such as `123` if the process should be started in run levels 1, 2 and 3. `Ondemand` entries may contain an A, B, or C. The `runlevel` field of `sysinit`, `boot`, and `bootwait` entries are ignored.

When the run level is changed, any running processes that are not specified for the new run level are killed, first with `SIGTERM` and then with `SIGKILL`.

EXAMPLES

This is an example of an `inittab` that resembles the old Linux `inittab`:

```
# inittab for linux
id:1:initdefault:
rc::bootwait:/etc/rc
1:1:respawn:/etc/getty 9600 tty1
2:1:respawn:/etc/getty 9600 tty2
3:1:respawn:/etc/getty 9600 tty3
4:1:respawn:/etc/getty 9600 tty4
```

This `inittab` file executes `/etc/rc` during boot and starts `gettys` on `tty1`–`tty4`.

A more elaborate `inittab` with different run levels (see the comments inside) is

```
#Level to run in
id:4:initdefault:
ud::boot:/etc/update
rc::bootwait:/etc/rc
cr::boot:/etc/crond
#
# level 1: getty on tty1
# level 2: getty on tty1-4
# level 3: tty1-4, dialin via modem(ttys2)
# level 4: tty1-4, ttyb
#
mr:126:once:/usr/bin/nodialin
mi:345:once:/usr/bin/dialin
1:1234:respawn:/etc/getty 9600 tty1
2:234:respawn:/etc/getty 9600 tty2
3:234:respawn:/etc/getty 9600 tty3
```

```
4:234:respawn:/etc/getty 9600 tty4
s2:3:respawn:/etc/mgetty ttys2 19200
b:4:respawn:/etc/getty 19200L ttyb
ca::ctrlaltdel:/etc/shutdown -t3 -rf now
```

inn.conf

inn.conf—Configuration data for InterNetNews programs.

DESCRIPTION

The file `/news/lib/inn.conf` is used to determine various parameters. Blank lines and lines starting with a number sign (#) are ignored. All other lines specify parameters that may be read and should be of the following form:

```
name : [optional whitespace] value
```

Everything after the whitespace and up to the end of the line is taken as the value; multi-word values should not be put in quotes. The case of names is significant; `server` is not the same as `Server` or `SERVER`.

Some parameters specified in the file may be overridden by environment variables, and some file parameters may be used to mask real data, such as when hiding a cluster of hosts behind a single electronic mail hostname. The current set of parameters is as follows:

fromhost	This is the name of the host to use when building the From header line. The default is the fully qualified domain name of the local host. The value of the FROMHOST environment variable, if it exists, overrides this.
moderatormailer	This names the default machine that contains forwarding aliases for all moderated groups. It is only used if the moderators(5) file doesn't exist or if the group is not matched by that file. The value is interpreted as a pattern match; see moderators(5).
organization	This specifies what to put in the Organization header if it is blank. The value of the ORGANIZATION environment variable, if it exists, overrides this.
pathhost	This specifies how to name the local site when building the Path header line. The default is the fully qualified domain name of the local host.
server	This specifies the name of the NNTP server to which an article should be posted. The value of the NNTPSERVER environment variable, if it exists, overrides this.
domain	This should be the domain name of the local host. It should not have a leading period, and it should not be a full host address. It is used only if the getFQDN routine in libinn(3) cannot get the fully qualified domain name by using either the gethostname(2) or gethostbyname(3) calls. The check is very simple; if either routine returns a name with a period in it, then it is assumed to have the full domain name.

Three parameters are used only by `nnrpd` when accepting postings from clients:

<code>mime-version</code>	If this parameter is present, then <code>nnrpd</code> will add the necessary MIME (Multipurpose Internet Mail Extensions) headers to all any articles that do not have a <code>Mime-Version</code> header. This parameter specifies the MIME version and should normally be <code>1.0</code> .
<code>mime-contenttype</code>	If MIME headers are being added, this parameter specifies the value of the <code>Content-Type</code> header. The default value is <code>text/plain; charset=US-ASCII</code> .
<code>mime-encoding</code>	If MIME headers are being added, this parameter specifies the value of the <code>Content-Transfer-Encoding</code> header. The default value is <code>7bit</code> .

Note that this file can be identical on all machines in an organization.

EXAMPLE

```
fromhost:          foo.com
moderatormailer:  %s@uunet.uu.net
organization:     Foo, Incorporated
#pathhost:        Use FQDN.
server:           news.foo.com
domain:           foo.com
```

This file is intended to be fairly static; any changes made to it are typically not reflected until a program restarts.

innwatchctl

`innwatchctl`—Control Usenet supervision by `innwatch`.

DESCRIPTION

The file `/news/lib/innwatchctl` is used to determine what actions are taken during the periodic supervisions by `innwatch`.

The file consists of a series of lines; blank lines and lines beginning with a number sign (`#`) are ignored. All other lines consist of seven fields, each preceded by a delimiting character:

```
:label:state:condition:test:limit:command:reason
```

The delimiter can be any one of several non-alphanumeric characters that does not appear elsewhere in the line; there is no way to quote it to include it in any of the fields. Any of `!`, `,`, `:`, `@`, `;`, or `?` is a good choice. Each line can have a different delimiter; the first character on each line is the delimiter for that line. Whitespace surrounding delimiters, except before the first, is ignored and does not form part of the fields; whitespace within fields is permitted. All delimiters must be present.

The first field is a label for the control line. It is used as an internal state indicator and in `ctlinn` messages to control the server. If omitted, the line number is used.

The second field specifies when this control line should be used. It consists of a list of labels and special indicators separated by whitespace. If the current state matches against any of the labels in this field, this line will be used as described below. The values that may be used are

- This line matches if the current state is the same as the label on this line, or if the current state is `run`, the initial state. This is also the default state if this field is empty.

+ This line matches if the current state is `run`.
 * This line always matches.
 label This line matches if the current state is the specified `label`.
 -label This line matches if the current state is not the specified `label`.

The third field specifies a shell command that is invoked if this line matches. Do not use any shell filename expansion characters such as `*`, `?`, or `[` (even quoted, they're not likely to work as intended). If the command succeeds, as indicated by its exit status, it is expected to have printed a single integer to standard output. This gives the value of this control line, to be used below. If the command fails, the line is ignored. The command is executed with its current directory set to the newsspool directory, `/news/spool`.

The fourth field specifies the operator to use to test the value returned above. It should be one of the two-letter numeric test operators defined in `test(1)` such as `eq`, `lt`, and the like. The leading dash (`-`) should not be included.

The fifth field specifies a constant with which to compare the value using the operator just defined. This is done by invoking the command

```
test value -operator constant
```

The line is said to “succeed” if it returns true.

The sixth field specifies what should be done if the line succeeds and in some cases if it fails. Any of the following words may be used:

<code>throttle</code>	Causes <code>innwatch</code> to throttle the server if this line succeeds. It also sets the state to the value of the line's label. If the line fails and the state was previously equal to the label on this line (that is, this line had previously succeeded), then a <code>go</code> command will be sent to the server, and <code>innwatch</code> will return to the <code>run</code> state. The <code>throttle</code> is only performed if the current state is <code>run</code> or a state other than the label of this line, regardless of whether the command succeeds.
<code>pause</code>	Is identical to <code>throttle</code> except that the server is paused.
<code>shutdown</code>	Sends a <code>shutdown</code> command to the server. It is for emergency use only.
<code>flush</code>	Sends a <code>flush</code> command to the server.
<code>go</code>	Causes <code>innwatch</code> to send a <code>go</code> command to the server and to set the state to <code>run</code> .
<code>exit</code>	Causes <code>innwatch</code> to exit.
<code>skip</code>	The result of the control file is skipped for the current pass.

The last field specifies the reason that is used in those `ctlindd` commands that require one. More strictly, it is part of the reason; `innwatch` appends some information to it. In order to enable other sites to recognize the state of the local `inn` server, this field should usually be set to one of several standard values. Use `No space` if the server is rejecting articles because of a lack of filesystem resources. Use `loadav` if the server is rejecting articles because of a lack of CPU resources.

Once `innwatch` has taken some action as a consequence of its control line, it skips the rest of the control file for this pass. If the action was to restart the server (that is, issue a `go` command), then the next pass will commence almost immediately so that `innwatch` can discover any other condition that may mean that the server should be suspended again.

EXAMPLES

```
@@@df .|awk 'NR==2 {print $4}'@lt@10000@throttle@No space
@@@df -i .|awk 'NR==2 {print $4}'@lt@1000@throttle@No space (inodes)
```

The first line causes the server to be throttled if the free space drops below 10000 units (using whatever units `df` uses) and restarted again when free space increases above the threshold.

The second line does the same for `inodes`.

The next three lines act as a group and should appear in the following order. It is easier to explain them, however, if they are described from the last up.

```
!load!load hload!loadavg!lt!5!go!
:hload:+ load:loadavg:gt:8:throttle:loadav
/load/+/loadavg/ge/6/pause/loadav
```

The final line causes the server to be paused if `innwatch` is in the `run` state and the load average rises to, or above, six. The state is set to `load` when this happens. The previous line causes the server to be throttled when `innwatch` is in the `run` or `load` state, and the load average rises above eight. The state is set to `hload` when this happens. Note that `innwatch` can switch the server from `paused` to `throttled` if the load average rises from below six to between six and seven and then to above eight. The first line causes the server to be sent a `go` command if `innwatch` is in the `load` or `hload` state and the load average drops below five.

Note that all three lines assume a mythical command `loadavg` that is assumed to print the current load average as an integer. In more practical circumstances, a pipe of `uptime` into `awk` is more likely to be useful.

BUGS

This file must be tailored for each individual site; the sample supplied is truly no more than a sample. The file should be ordered so that the more common problems are tested first.

The `run` state is not actually identified by the label with that three letter name, and using it will not work as expected.

Using an “unusual” character for the delimiter such as `(, *, &, "`, and the like is likely to lead to obscure and hard-to-locate bugs.

ipc

`ipc`—System V interprocess communication mechanisms.

SYNOPSIS

```
# include <sys/types.h>
# include <sys/ipc.h>
# include <sys/msg.h>
# include <sys/sem.h>
# include <sys/shm.h>
```

DESCRIPTION

The manual page refers to the Linux implementation of the System V interprocess communication mechanisms: message queues, semaphore sets, and shared memory segments. In the following, the word `resource` means an instantiation of one among such mechanisms.

RESOURCE ACCESS PERMISSIONS

For each resource, the system uses a common structure of type `struct ipc_perm` to store information needed in determining permissions to perform an `ipc` operation. The `ipc_perm` structure, defined by the `<sys/ipc.h>` system header file, includes the following members:

```
ushort cuid; /* creator user id */
ushort cgid; /* creator group id */
ushort uid; /* owner user id */
ushort gid; /* owner group id */
ushort mode; /* r/w permissions */
```

The mode member of the `ipc_perm` structure defines, with its lower nine bits, the access permissions to the resource for a process executing an `ipc` system call. The permissions are interpreted as follows:

0400	Read by user.
0200	Write by user.
0040	Read by group.
0020	Write by group.
0004	Read by others.
0002	Write by others.

Bits 0100, 0010, and 0001 (the execute bits) are unused by the system. Furthermore “write” effectively means “alter” for a semaphore set.

The same system header file defines also the following symbolic constants:

IPC_CREAT	Create entry if key doesn't exist.
IPC_EXCL	Fail if key exists.
IPC_NOWAIT	Error if request must wait.
IPC_PRIVATE	Private key.
IPC_RMID	Remove resource.
IPC_SET	Set resource options.
IPC_STAT	Get resource options.

Note that `IPC_PRIVATE` is a `key_t` type, whereas all the others symbolic constants are flag fields ORable into an `int` type variable.

MESSAGE QUEUES

A message queue is uniquely identified by a positive integer (its `msqid`) and has an associated data structure of type `struct msqid_ds`, defined in `<sys/msg.h>`, containing the following members:

```
struct ipc_perm msg_perm;
ushort msg_qnum; /* no of messages on queue */
ushort msg_qbytes; /* bytes max on a queue */
ushort msg_lspid; /* pid of last msgsnd call */
ushort msg_lrpid; /* pid of last msgrcv call */
time_t msg_stime; /* last msgsnd time */
time_t msg_rtime; /* last msgrcv time */
time_t msg_ctime; /* last change time */
```

<code>msg_perm</code>	<code>ipc_perm</code> structure that specifies the access permissions on the message queue.
<code>msg_qnum</code>	Number of messages currently on the message queue.
<code>msg_qbytes</code>	Maximum number of bytes of message text allowed on the message queue.
<code>msg_lspid</code>	ID of the process that performed the last <code>msgsnd</code> system call.
<code>msg_lrpid</code>	ID of the process that performed the last <code>msgrcv</code> system call.
<code>msg_stime</code>	Time of the last <code>msgsnd</code> system call.
<code>msg_rtime</code>	Time of the last <code>msgrcv</code> system call.
<code>msg_ctime</code>	Time of the last system call that changed a member of the <code>msqid_ds</code> structure.

SEMAPHORE SETS

A semaphore set is uniquely identified by a positive integer (its `semid`) and has an associated data structure of type `struct semid_ds`, defined in `<sys/sem.h>`, containing the following members:

```
struct ipc_perm sem_perm;
time_t sem_otime; /* last operation time */
```

```
time_t sem_ctime; /* last change time */
ushort sem_nsems; /* count of sems in set */

sem_perm          ipc_perm structure that specifies the access permissions on the semaphore set.
sem_otime         Time of last semop system call.
sem_ctime         Time of last semctl system call that changed a member of the above structure or of one
                  semaphore belonging to the set.
sem_nsems         Number of semaphores in the set. Each semaphore of the set is referenced by a non-negative
                  integer ranging from 0 to sem_nsems-1.
```

A semaphore is a data structure of type `struct sem` containing the following members:

```
ushort semval; /* semaphore value */
short sempid; /* pid for last operation */
ushort semncnt; /* no. of awaiting semval to increase */
ushort semzcnt; /* no. of awaiting semval = 0 */

semval            Semaphore value: a non-negative integer.
sempid            ID of the last process that performed a semaphore operation on this semaphore.
semncnt           Number of processes suspended awaiting for semval to increase.
semznt            Number of processes suspended awaiting for semval to become zero.
```

SHARED MEMORY SEGMENTS

A shared memory segment is uniquely identified by a positive integer (its `shmid`) and has an associated data structure of type `struct shmid_ds`, defined in `<sys/shm.h>`, containing the following members:

```
struct ipc_perm shm_perm;
int shm_segsz; /* size of segment */
ushort shm_cpid; /* pid of creator */
ushort shm_lpid; /* pid, last operation */
short shm_nattch; /* no. of current attaches */
time_t shm_atime; /* time of last attach */
time_t shm_dtime; /* time of last detach */
time_t shm_ctime; /* time of last change */

shm_perm          ipc_perm structure that specifies the access permissions on the shared memory segment.
shm_segsz         Size in bytes of the shared memory segment.
shm_cpid          ID of the process that created the shared memory segment.
shm_lpid          ID of the last process that executed a shmat or shmdt system call.
shm_nattch        Number of current alive attaches for this shared memory segment.
shm_atime         Time of the last shmat system call.
shm_dtime         Time of the last shmdt system call.
shm_ctime         Time of the last shmctl system call that changed shmid_ds.
```

Linux 0.99.13, 1 November 1993

issue

`issue`—Issue identification file.

DESCRIPTION

The file `/etc/issue` is a text file that contains a message or system identification to be printed before the login prompt. It may contain various `@char` and `\char` sequences if supported by `getty(1)`.

FILES

`/etc/issue`

SEE ALSO

Linux, 24 July 1993

lilo.conf

`lilo.conf`—Configuration file for LILO.

DESCRIPTION

This file, by default `/etc/lilo.conf`, is read by the boot loader installer LILO (see `lilo(8)`).

It might look as follows:

```
boot = /dev/hda
delay = 40
compact
vga = normal
root = /dev/hda1
read-only
image = /zImage-1.5.99
        label = try
image = /zImage-1.0.9
        label = 1.0.9
image = /tamuvmlinux
        label = tamu
        root = /dev/hdb2
        vga = ask
other = /dev/hda3
        label = dos
        table = /dev/hda
```

This configuration file specifies that LILO uses the Master Boot Record on `/dev/hda`. (For a discussion of the various ways to use LILO and the interaction with other operating systems, see `user.tex` from the LILO documentation.)

When booting, the boot loader will wait 4 seconds (40 deciseconds) for you to press Shift. If you don't, then the first kernel image mentioned (`/zImage-1.5.99`, which you probably installed just 5 minutes ago) will be booted. If you do, the boot loader will ask you which image to boot. In case you forgot the possible choices, press Tab (or ? if you have a U.S. keyboard), and you will be presented with a menu. You now have the choice of booting this brand new kernel, an old trusted kernel, or a kernel on another root file system (just in case you did something stupid on your usual root) or booting a different operating system. There can be up to 16 images mentioned in `lilo.conf`.

As can be seen previously, a configuration file starts with a number of global options (the top six lines in the example), followed by descriptions of the options for the various images. An option in an image description will override a global option.

GLOBAL OPTIONS

There are many possible keywords. The description that follows is almost literally from `user.tex` (just slightly abbreviated):

<code>backup=backup-file</code>	Copy the original boot sector to <code>backup-file</code> (which may also be a device, such as <code>/dev/nul1</code>) instead of <code>/boot/boot.NNNN</code> .
<code>boot=boot-device</code>	Sets the name of the device (such as a hard disk partition) that contains the boot sector. If this keyword is omitted, the boot sector is read from (and possibly written to) the device that is currently mounted as root.
<code>compact</code>	Tries to merge read requests for adjacent sectors into a single read request. This drastically reduces load time and keeps the map smaller. Using <code>compact</code> is especially recommended when booting from a floppy disk.
<code>default=name</code>	Uses the specified image as the default boot image. If <code>default</code> is omitted, the image appearing first in the configuration file is used.
<code>delay=tsecs</code>	Specifies the number of tenths of a second the boot loader should wait before booting the first image. This is useful on systems that immediately boot from the hard disk after enabling the keyboard. The boot loader doesn't wait if <code>delay</code> is omitted or is set to zero.
<code>disk=device-name</code>	Defines non-standard parameters for the specified disk. See section "Disk Geometry" of <code>user.tex</code> for details.
<code>disktab=disktab-file</code>	Specifies the name of the disk parameter table. The map installer looks for <code>/etc/disktab</code> if <code>disktab</code> is omitted. The use of <code>disktabs</code> is discouraged.
<code>fix-table</code>	This allows LILO to adjust 3-D addresses in partition tables. Each partition entry contains a 3-D (sector/head/cylinder) and a linear address of the first and the last sector of the partition. If a partition is not track-aligned and if certain other operating systems (such as PC/MS-DOS or OS/2) are using the same disk, they may change the 3-D address. LILO can store its boot sector only on partitions where both address types correspond. LILO readjusts incorrect 3-D start addresses if <code>fix-table</code> is set. Warning: This does not guarantee that other operating systems may not attempt to reset the address later. It is also possible that this change has other, unexpected side effects. The correct fix is to repartition the drive with a program that does align partitions to tracks. Also, with some disks (such as some large EIDE disks with address translation enabled), under some circumstances, it may even be unavoidable to have conflicting partition table entries.
<code>force-backup=backup-file</code>	Like <code>backup</code> but overwrite an old backup copy if it exists.
<code>ignore-table</code>	Tells LILO to ignore corrupt partition tables.
<code>install=boot-sector</code>	Install the specified file as the new boot sector. If <code>install</code> is omitted, <code>/boot/boot.b</code> is used as the default.
<code>linear</code>	Generate linear sector addresses instead of sector/head/cylinder addresses. Linear addresses are translated at runtime and do not depend on disk geometry. Note that boot disks may not be portable if <code>linear</code> is used because the BIOS service to determine the disk geometry does not work reliably for floppy disks. When using <code>linear</code> with large disks, <code>/sbin/lilo</code> may generate references to inaccessible disk areas because 3-D sector addresses are not known before boot time.
<code>lock</code>	Enables automatic recording of boot command lines as the defaults for the following boots. This way, LILO "locks" on a choice until it is manually overridden.
<code>map=map-file</code>	Specifies the location of the map file. If <code>map</code> is omitted, the file <code>/boot/map</code> is used.
<code>message=message-file</code>	Specifies a file containing a message that is displayed before the boot prompt. No message is displayed while waiting for a shifting key after printing <code>LILO</code> . In the message, the <code>FF</code> character (Ctrl+L) clears the local screen. The size of the message file is limited to 65,535 bytes. The map file has to be rebuilt if the message file is changed or moved.
<code>nowarn</code>	Disables warnings about possible future dangers.

optional	The per-image option <code>optional</code> applies to all images.
password=password	The per-image option <code>password=...</code> applies to all images.
prompt	Forces entering the boot prompt without expecting any prior key presses. Unattended reboots are impossible if <code>prompt</code> is set and <code>timeout</code> isn't.
restricted	The per-image option <code>restricted</code> applies to all images.
serial=parameters	Enables control from a serial line. The specified serial port is initialized and the boot loader is accepting input from it and from the PC's keyboard. Sending a break on the serial line corresponds to pressing a Shift key on the console in order to get the boot loader's attention. All boot images should be password-protected if the serial access is less secure than access to the console, such as if the line is connected to a modem. The parameter string has the following syntax: <pre><port>[,<bps>[<parity>[<bits>]]]</pre> <p><code><port></code>: The number of the serial port, zero-based. 0 corresponds to COM1 alias <code>/dev/ttyS0</code>, and so on. All four ports can be used (if present). <code><bps></code>: The baud rate of the serial port. The following baud rates are supported: 110, 150, 300, 600, 1200, 2400, 4800, and 9600 bps. Default is 2400 bps.</p> <p><code><parity></code>: The parity used on the serial line. The boot loader ignores input parity and strips the eighth bit. The following (uppercase or lowercase) characters are used to describe the parity: <code>n</code> for no parity, <code>e</code> for even parity, and <code>o</code> for odd parity.</p> <p><code><bits></code>: The number of bits in a character. Only 7 and 8 bits are supported. Default is 8 if parity is none and 7 if parity is even or odd.</p> <p>If <code>serial</code> is set, the value of <code>delay</code> is automatically raised to 20. For example, <code>serial=0,2400n8</code> initializes COM1 with the default parameters.</p>
timeout=tsecs	Sets a time-out (in tenths of a second) for keyboard input. If no key is pressed for the specified time, the first image is automatically booted. Similarly, password input is aborted if the user is idle for too long. The default time-out is infinite.
verbose=level	Turns on a lot of progress reporting. Higher numbers give more verbose output. If <code>-v</code> is additionally specified on the LILO command line, the level is increased accordingly. The maximum verbosity level is 5.

Additionally, the kernel configuration parameters `append`, `ramdisk`, `read-only`, `read-write`, `root`, and `vga` can be set in the global options section. They are used as defaults if they aren't specified in the configuration sections of the respective kernel images.

PER-IMAGE SECTION

A per-image section starts with either a line

```
image=pathname
```

to indicate a file or device containing the boot image of a Linux kernel or a line

```
other=pathname
```

to indicate an arbitrary system to boot.

In the former case, if an `image` line specifies booting from a device, then one has to indicate the range of sectors to be mapped using

```
range=start-end
```

In the latter case (booting another system), there are the three options:

```
loader=chain-loader
```

This specifies the chain loader that should be used. By default, `/boot/chain.b` is used. The chain loader must be specified if booting from a device other than the first hard or floppy disk.

<code>table=device</code>	This specifies the device that contains the partition table. The boot loader will not pass partition information to the booted operating system if this variable is omitted. (Some operating systems have other means to determine from which partition they have been booted. For example, MS-DOS usually stores the geometry of the boot disk or partition in its boot sector.) Note that <code>/sbin/lilo</code> must be rerun if a partition table mapped referenced with <code>table</code> is modified.
<code>unsafe</code>	Do not access the boot sector at map creation time. This disables some sanity checks, including a partition table check. If the boot sector is on a fixed-format floppy disk device, using <code>UNSAFE</code> avoids the need to put a readable disk into the drive when running the map installer. <code>unsafe</code> and <code>table</code> are mutually incompatible.

In both cases, the following options apply:

<code>label=name</code>	The boot loader uses the main file <code>name</code> (without its path) of each image specification to identify that image. A different name can be used by setting the variable <code>label</code> .
<code>alias=name</code>	A second name for the same entry can be used by specifying an alias.
<code>lock</code>	(See previous description.)
<code>optional</code>	Omit the image if it is not available at map creation time. This is useful to specify test kernels that are not always present.
<code>password=password</code>	Protect the image by a password.
<code>restricted</code>	A password is only required to boot the image if parameters are specified on the command line (such as <code>single</code>).

KERNEL OPTIONS

If the booted image is a Linux kernel, then one may pass command-line parameters to this kernel.

<code>append=string</code>	Appends the options specified to the parameter line passed to the kernel. This is typically used to specify parameters of hardware that can't be entirely autodetected or for which probing may be dangerous. Example: <code>append = "hd=64,32,202"</code> .
<code>literal=string</code>	Like <code>append</code> but removes all other options (such as setting of the root device). Because vital options can be removed unintentionally with <code>literal</code> , this option cannot be set in the global options section.
<code>ramdisk=size</code>	This specifies the size of the optional RAM disk. A value of zero indicates that no RAM disk should be created. If this variable is omitted, the RAM disk size configured into the boot image is used.
<code>read-only</code>	This specifies that the root filesystem should be mounted read-only. Typically, the system startup procedure remounts the root filesystem read-write later (such as after <code>fscking</code> it).
<code>read-write</code>	This specifies that the root filesystem should be mounted read-write.
<code>root=root-device</code>	This specifies the device that should be mounted as root. If the special name <code>current</code> is used, the root device is set to the device on which the root filesystem is currently mounted. If the root has been changed with <code>-r</code> , the respective device is used. If the variable <code>root</code> is omitted, the root device setting contained in the kernel image is used. (That is set at compile time using the <code>ROOT_DEV</code> variable in the kernel makefile and can later be changed with the <code>rdev(8)</code> program.)
<code>vga=mode</code>	This specifies the VGA text mode that should be selected when booting. The following values are recognized (case is ignored): <code>normal</code> : Select normal 80x25 text mode. <code>extended</code> (or <code>ext</code>): Select 80x50 text mode. <code>ask</code> : Stop and ask for user input (at boot time). <code><number></code> : Use the corresponding text mode. A list of available modes can be obtained by booting with <code>vga=ask</code> and pressing Enter.

If this variable is omitted, the VGA mode setting contained in the kernel image is used. (That is set at compile time using the `SVGA_MODE` variable in the kernel makefile and can later be changed with the `rdev(8)` program.)

MAKEDEV.cfg

`MAKEDEV.cfg`—Configuration for `MAKEDEV(8)`.

DESCRIPTION

`MAKEDEV.cfg` is a text file that tells `MAKEDEV(8)` what to do (and equally importantly, what not to do). Unlike `DEVINFO(5)`, which is meant to be centrally maintained, it contains all local configuration for a particular site and all customization. There are basically two kinds of declaration in this file: a “class” declaration and an “omit” declaration.

A class declaration has the form

```
class name : owner group-owner permissions
```

This says that any devices placed in the specified class by `DEVINFO` should be created with this ownership and these permissions. A sample entry might be

```
class public: root system 0666
```

This says that devices marked `public` should be owned by `root.system` and have mode `666`.

An omit declaration has the form

```
omit { device... }
```

This causes the specified devices to never be created, even if explicitly specified. Use caution when setting this up. The intent is to be able to run `MAKEDEV update` and not have it create all sorts of useless devices you’d never use.

Version 1.4, January 1995

moderators

`moderators`—Mail addresses for moderated Usenet newsgroups.

DESCRIPTION

The `GetModeratorAddress(3)` routine reads the file `/news/lib/moderators` to determine how to reach the moderator of a newsgroup. This is used by `inews(1)` when an unapproved local posting is made to a moderated newsgroup.

The file is read until a match is found. Blank lines and lines starting with a number sign (`#`) are ignored. All other lines should consist of two fields separated by a colon.

The first field is a `wildmat(3)`-style pattern. If it matches the name of the newsgroup, then the second field is taken to be a format string for `sprintf(3)`. This string should have at most one `%s` parameter, which will be given the name of the newsgroup with periods transliterated to dashes.

Here is a sample file:

```
foo.important:announce-request@foo.com
foo.*:%s@mailer.foo.com
gnu.*:%s@prep.ai.mit.edu
:%s@uunet.uu.net
```

Using this file, postings to the moderated newsgroup in the left column will be sent to the address shown in the right column:

```
foo.important announce-request@foo.com
foo.x.announce foo-x-announce@mailer.foo.com
gnu.emacs.sources gnu-emacs-sources@prep.ai.mit.edu
comp.sources.unix comp-sources-unix@uunet.uu.net
```

/etc/modules

`/etc/modules`—Kernel modules to load at boot time.

DESCRIPTION

The `/etc/modules` file contains the names of kernel modules that are to be loaded at boot time, one per line. Comments begin with a #, and everything on the line after them are ignored.

Debian GNU/Linux version 0.93

motd

`motd`—Message of the day.

DESCRIPTION

The contents of `/etc/motd` are displayed by `login(1)` after a successful login but just before it executes the login shell.

The `motd` stands for “message of the day,” and this file has been traditionally been used for exactly that. (It requires much less disk space than mail to all users.)

FILES

`/etc/motd`

`login(1)` `issue(5)`

Linux, 29 December 1992

mtools

`mtools`—Table of DOS devices.

DESCRIPTION

`/etc/mtools.conf` and `~/.mtoolsrc` are the configuration files for `mtools`. These configuration files describe the following items:

- Global configuration flags and variables
- Per-drive flags and variables
- Character translation tables

`/etc/mtools.conf` is the system-wide configuration file, and `~/.mtoolsrc` is the user's private configuration file.

GENERAL SYNTAX

The configuration files is made up of sections. Each section starts with a keyword identifying the section followed by a colon. Then follow variable assignments and flags. Variable assignments take the following form:

```
name=value
```

Flags are lone keywords without an equal sign and `value` following them. A section either ends at the end of the file or where the next section begins.

Lines starting with a hash (`#`) are comments. Newline characters are equivalent to whitespace (except where ending a comment). The configuration file is case insensitive, except for items enclosed in quotes (such as filenames).

DEFAULT VALUES

For most platforms, `mtools` contains reasonable compiled-in defaults. You usually don't need to bother with the configuration file, if all you want to do with `mtools` is access your floppy drives. On the other hand, the configuration file is needed if you also want to use `mtools` to access your hard disk partitions and `dosemu` image files.

GLOBAL VARIABLES

Global variables may be set to `1` or to `0`.

The following global flags are recognized:

<code>MTTOOLS_SKIP_CHECK</code>	If this is set to <code>1</code> , <code>mtools</code> skips most of its sanity checks. This is needed to read some Atari disks that have been made with the earlier ROMs and that would not be recognized otherwise.
<code>MTTOOLS_FAT_COMPATIBILITY</code>	If this is set to <code>1</code> , <code>mtools</code> skips the FAT size checks. Some disks have a bigger FAT than they really need. These are rejected if this option is not set.
<code>MTTOOLS_LOWER_CASE</code>	If this is set to <code>1</code> , <code>mtools</code> displays all-uppercase short filenames as lowercase. This has been done to allow a behavior that is consistent with older versions of <code>mtools</code> , which didn't know about the case bits.

For example, inserting the following line into your configuration file instructs `mtools` to skip the sanity checks:

```
MTTOOLS_SKIP_CHECK=1.
```

Global variables may also be set via the environment: `export MTTOOLS_SKIP_CHECK=1.`

PER-DRIVE FLAGS AND VARIABLES

Per-drive flags and values may be described in a drive section. A drive section starts with `drive driveletter:`.

Then follow variable-value pairs and flags.

GENERAL PURPOSE DRIVE VARIABLES

The following variables are available:

<code>file</code>	The name of the file or device holding the disk image. This is mandatory. The filename should be enclosed in quotes.
-------------------	--

<code>use_xdf</code>	If this is set to a nonzero value, <code>mttools</code> also tries to access this disk as an Xdf disk. Xdf is a high-capacity format used by OS/2. This is off by default.
<code>partition</code>	Tells <code>mttools</code> to treat the drive as a partitioned device and to use the given partition. Only primary partitions are accessible using this method, and they are numbered from 1 to 4. For logical partitions, use the more general <code>offset</code> variable. The <code>partition</code> variable is intended for Syquests, ZIP drives, and DOSEMU hdimages. It is not recommended for hard disks to which direct access to partitions is available.
<code>offset</code>	Describes where in the file the MS-DOS filesystem starts. This is useful for logical partitions in DOSEMU hdimages and for ATARI RAM disks. By default, this is zero, meaning that the filesystem starts right at the beginning of the device or file.
<code>fat_bits</code>	The number of FAT bits. This can be 12 or 16. This is very rarely needed because it can almost always be deduced from information in the boot sector. On the contrary, describing the number of fat bits can actually be harmful if you get it wrong. You should only use it if <code>mttools</code> gets the autodetected number of fat bits wrong or if you want to <code>mformat</code> a disk with a weird number of fat bits.

Only the `file` option is mandatory. The other parameters may be left out. In that case, a default value or an autodetected value is used.

DRIVE GEOMETRY CONFIGURATION

Geometry information describes the physical characteristics about the disk. Its has three purposes:

<code>mformat</code>	The geometry information is written into the boot sector of the newly made disk. However, you may also describe the geometry information on the command line. See <code>mformat(1)</code> for details.
<code>filtering</code>	<p>On some Unices, device nodes only support one physical geometry. The geometry is compared to the actual geometry stored on the boot sector to make sure that this device node is able to correctly read the disk. If the geometry doesn't match, this drive entry fails, and the next drive entry bearing the same drive letter is tried. See the next section "Supplying Multiple Descriptions for a Drive" for more details on supplying several descriptions for a drive letter.</p> <p>If no geometry information is supplied in the configuration file, all disks are accepted. On Linux (and on Sparc), there exist device nodes with configurable geometry (<code>/dev/fd0</code>, <code>/dev/fd1</code> etc), so filtering is not needed (and ignored) for disk drives. (<code>mttools</code> still does do filtering on plain files (disk images) in Linux: This is mainly intended for test purposes because I don't have access to a UNIX that would actually need filtering.)</p>
<code>initial geometry</code>	The geometry information (if available) is also used to set the initial geometry on configurable device nodes. This initial geometry is used to read the boot sector, which contains the real geometry. If no geometry information is supplied in the configuration file, no initial configuration is done. On Linux, this is not really needed either because the configurable devices are able to autodetect the disk type accurately enough (for most common formats) to read the boot sector.

Wrong geometry information may lead to very bizarre errors. That's why I strongly recommend that you don't use geometry configuration unless you really need it.

The following geometry related variables are available:

<code>cylinders</code>	The number of cylinders.
<code>heads</code>	The number of heads (sides).
<code>sectors</code>	The number of sectors per track.

For example, the following drive section describes a 1.44M drive:

```
drive a:
file="/dev/fd0H1440"
fat_bits=12
tracks=80 heads=2 sectors=18
```

The following shorthand geometry descriptions are available:

1.44M	High density, 3 1/2 disk. Equivalent to fat_bits=12 tracks=80 heads=2 sectors=18.
1.2M	High density, 5 1/4 disk. Equivalent to fat_bits=12 tracks=80 heads=2 sectors=15.
720K	Double density, 3 1/2 disk. Equivalent to fat_bits=12 tracks=80 heads=2 sectors=9.
360K	Double density, 5 1/4 disk. Equivalent to fat_bits=12 tracks=40 heads=2 sectors=9.

The shorthand format descriptions may be amended. For example, 360K sectors=8 describes a 320K disk and is equivalent to fat_bits=12 tracks=40 heads=2 sectors=8.

OPEN FLAGS

Moreover, the following flags are available:

sync	All I/O operations are done synchronously.
nodelay	The device or file is opened with the <code>O_NDELAY</code> flag. This is needed on some non-Linux architectures.
exclusive	The device or file is opened with the <code>O_EXCL</code> flag. On Linux, this ensures exclusive access to the floppy drive. On most other architectures and for plain files, it has no effect at all.

SUPPLYING MULTIPLE DESCRIPTIONS FOR A DRIVE

It is possible to supply multiple descriptions for a drive. In that case, the descriptions are tried in order until one is found that fits. Descriptions may fail for several reasons:

- The geometry is not appropriate
- There is no disk in the drive
- Other problems

Multiple definitions are useful when using physical devices that are only able to support one single disk geometry:

```
drive a: file="/dev/fd0H1440" 1.44m
drive a: file="/dev/fd0H720" 720k
```

This instructs mtools to use `/dev/fd0H1440` for 1.44M (high density) disks and `/dev/fd0H720` for 720K (double density) disks. On Linux, this feature is not really needed because the `/dev/fd0` device is able to handle any geometry.

You can also use multiple drive descriptions to access both of your physical drives through one drive letter:

```
drive z: file="/dev/fd0"
drive z: file="/dev/fd1"
```

With this description, `mdir z:` accesses your first physical drive if it contains a disk. If the first drive doesn't contain a disk, mtools checks the second drive.

When using multiple configuration files, drive descriptions in the files parsed last override descriptions for the same drive in earlier files. In order to avoid this, use the `drive+` or `+drive` keywords instead of `drive`. The first adds a description to the end of the list (will be tried last), and the second adds it to the start of the list.

CHARACTER TRANSLATION TABLES

If you live in the USA, in Western Europe, or in Australia, you can skip this section.

INTRODUCTION

DOS uses a different character code mapping from UNIX. Seven-bit characters still have the same meaning; only characters with the eight-bit set are affected. To make matters worse, there are several translation tables available depending on the country where you are. The appearance of the characters is defined using code pages. These code pages aren't the same for all countries. For instance, some code pages don't contain upper -case accented characters. On the other hand, some code pages contain characters that don't exist in UNIX, such as certain line-drawing characters or accented consonants used by some Eastern European countries. This affects two things relating to filenames:

Uppercase characters	In short names, only uppercase characters are allowed. This also holds for accented characters. For instance, in a code page that doesn't contain accented uppercase characters, the accented lowercase characters get transformed into their unaccented counterparts.
Long filenames	Microsoft has finally come to their senses and uses a more standard mapping for the long filenames. They use Unicode, which is basically a 32-bit version of ASCII. Its first 256 characters are identical to UNIX ASCII. Thus, the code page also affects the correspondence between the codes used in long names and those used in short names.

`mttools` considers the filenames entered on the command line as having the UNIX mapping and translates the characters to get short names. By default, code page 850 is used with the Swiss uppercase/lowercase mapping. I chose this code page because its set of existing characters most closely matches UNIX's. Moreover, this code page covers most characters in use in the USA, Australia, and Western Europe. However, it is still possible to chose a different mapping. There are two methods: the `country` variable and explicit tables.

CONFIGURATION USING COUNTRY

The `COUNTRY` variable is recommended for people that also have access to MS-DOS system files and documentation. If you don't have access to these, I'd suggest you use explicit tables instead.

Syntax: `COUNTRY=" country [, [codepage], country.sys]"`

This tells `mttools` to use a UNIX-to-DOS translation table that matches `codepage` and an lowercase-to-uppercase table for `country` and to use the `country.sys` file to get the lowercase-to-uppercase table. The `country` code is most often the telephone prefix of the country. Refer to the DOS help page on `country` for more details. The `codepage` and the `country.sys` parameters are optional. Don't type in the square brackets; they are only there to indicate which parameters are optional. The `country.sys` file is supplied with MS-DOS. In most cases, you don't need it because the most common translation tables are compiled into `mttools`. Don't worry if you run a UNIX-only box that lacks this file.

If `codepage` is not given, a per-country default code page is used. If the `country.sys` parameter isn't given, compiled-in defaults are used for the lowercase-to-uppercase table. This is useful for other Unices than Linux, which may have no `country.sys` file available online.

The UNIX-to-DOS are not contained in the `country.sys` file, and thus `mttools` always uses compiled-in defaults for those. Thus, only a limited amount of code pages are supported. If your preferred code page is missing, or if you know the name of the Windows 95 file that contains this mapping, drop me a line at Alain.Knaeff@inrialpes.fr.

The `COUNTRY` variable can also be set using the environment.

CONFIGURATION USING EXPLICIT TRANSLATION TABLES

Translation tables may be described in lines in the configuration file. Two tables are needed: first the DOS-to-UNIX table and then the lowercase-to-uppercase table. A DOS-to-UNIX table starts with the `tounix` keyword, followed by a colon and 128 hexadecimal numbers. A lower-to-upper table starts with the `fucase` keyword, followed by a colon and 128 hexadecimal numbers.

The tables only show the translations for characters whose codes is greater than 128 because translation for lower codes is trivial. Example:

tounix:

```
0xc7 0xfc 0xe9 0xe2 0xe4 0xe0 0xe5 0xe7
0xea 0xeb 0xe8 0xef 0xee 0xec 0xc4 0xc5
0xc9 0xe6 0xc6 0xf4 0xf6 0xf2 0xfb 0xf9
0xff 0xd6 0xdc 0xf8 0xa3 0xd8 0xd7 0x5f
0xe1 0xed 0xf3 0xfa 0xf1 0xd1 0xaa 0xba
0xbf 0xae 0xac 0xbd 0xbc 0xa1 0xab 0xbb

```

The first table maps DOS character codes to UNIX character codes. For example, the DOS character number 129 is a u with two dots on top of it. To translate it into UNIX, we look at the character number 1 in the first table (1 = 129 - 128). This is 0xfc. (Beware; numbering starts at 0.) The second table maps lowercase DOS characters to uppercase DOS characters. The same lowercase u with dots maps to character 0x9a, which is an uppercase U with dots in DOS.

UNICODE CHARACTERS GREATER THAN 256

If an existing MS-DOS name contains Unicode character greater than 256, these are translated to underscores or to characters that are close in visual appearance. For example, accented consonants are translated into their unaccented counterparts. This translation is used for `mdir` and for the UNIX filenames generated by `mcopy`. Linux does support Unicode too, but unfortunately, too few applications support it yet to bother with it in `mtools`. Most importantly, `xterm` can't display Unicode yet. If there is sufficient demand, I might include support for Unicode in the UNIX filenames as well.

Caution: When deleting files with `mtools`, the underscore matches all characters that can't be represented in UNIX. Be careful before `mdel!`

LOCATION OF CONFIGURATION FILES AND PARSING ORDER

The configuration files are parsed in the following order:

Compiled-in defaults

```

/etc/mtools.conf
/etc/mtools. This is for backwards compatibility only and is only parsed if mtools.conf doesn't exist.
-/.mtoolsrc

```

Options described in the later files override those described in the earlier files. Drives defined in earlier files persist if they are not overridden in the later files. For instance, drives A and B may be defined in `/etc/mtools.conf` and drives C and D may be defined in `-.mtoolsrc`. However, if `-.mtoolsrc` also defines drive A, this new description would override the description of drive A in `/etc/mtools.conf` instead of adding to it. If you want to add a new description to a drive already described in an earlier file, you need to use either the `+drive` or `drive+` keywords.

BACKWARDS COMPATIBILITY

The syntax described herein is new for version `mtools 2.5.4`. The old line-oriented syntax is still supported. Each line beginning with a single letter is considered to be a drive description using the old syntax. Old style and new style drive sections may be mixed within the same configuration file to make upgrading easier. Support for the old syntax will be phased out eventually, and to discourage its use, I purposefully omit its description here.

FILES

```

/etc/mtools.conf
-/.mtoolsrc

```

newsfeeds

`newsfeeds`—Determine where Usenet articles get sent.

DESCRIPTION

The file `/news/lib/newsfeeds` specifies how incoming articles should be distributed to other sites. It is parsed by the InterNetNews server `inn(8)` when it starts up or when directed to by `ctlinn(8)`.

The file is interpreted as a set of lines according to the following rules. If a line ends with a backslash, then the backslash, the newline, and any whitespace at the start of the next line is deleted. This is repeated until the entire “logical” line is collected. If the logical line is blank or starts with a number sign (`#`), it is ignored.

All other lines are interpreted as feed entries. An entry should consist of four colon-separated fields; two of the fields may have optional subfields, marked off by a slash. Fields or subfields that take multiple parameters should be separated by a comma. Extra whitespace can cause problems. Except for the site names, case is significant. The format of an entry is

```

si tename[/exclude,exclude,...]
:pattern,pattern...[/distrib,distrib...]\
:flag,flag...\
:param

```

Each field is described below.

The `si tename` is the name of the site to which a news article can be sent. It is used for writing log entries and for determining if an article should be forwarded to a site. If `si tename` already appears in the article's Path header, then the article will not be sent to the site. The name is usually whatever the remote site uses to identify itself in the Path line but can be almost any word that makes sense; special local entries (such as archivers or gateways) should probably end with an exclamation point to make sure that they do not have the same name as any real site. For example, `gateway` is an obvious name for the local entry that forwards articles out to a mailing list. If a site with the name `gateway` posts an article, when the local site receives the

article, it will see the name in the Path and not send the article to its own gateway entry. If an entry has an exclusion subfield, then the article will not be sent to that site if any of the names specified as excludes appear in the Path header. The same sitename can be used more than once; the appropriate action will be taken for each site that should receive the article, regardless of the name, although this is recommended only for program feeds to avoid confusion. Case is not significant in site names.

The patterns specify which groups to send to the site and are interpreted to build a “subscription list” for the site. The default subscription is to get all groups. The patterns in the field are wildmat(3)-style patterns and are matched in order against the list of newsgroups that the local site receives. If the first character of a pattern is an exclamation mark, then any groups matching the pattern are removed from the subscription; otherwise, any matching groups are added. For example, to receive all comp groups but only comp.sources.unix within the sources newsgroups, the following set of patterns can be used:

```
comp.*,!comp.sources.*,comp.sources.unix
```

There are three things to note about this example. The first is that the trailing .* is required. The second is that, again, the result of the last match is the most important. The third is that comp.sources.* could be written as comp.sources*, but this would not have the same effect if there were a comp.sources-only group.

See innd(8) for details on the propagation of control messages.

A subscription can be further modified by specifying “distributions” that the site should or should not receive. The default is to send all articles to all sites that subscribe to any of the groups where it has been posted, but if an article has a Distribution header and any distrib is specified, then they are checked according to the following rules:

1. If the Distribution header matches any of the values in the subfield, then the article is sent.
2. If a distrib starts with an exclamation point and it matches the Distribution header, then the article is not sent.
3. If Distribution header does not match any distrib in the site’s entry and no negations were used, then the article is not sent.
4. If Distribution header does not match any distrib in the site’s entry and any distrib started with an exclamation point, then the article is sent.

If an article has more than one distribution specified, then each one is evaluated according to the preceding rules. If any of the specified distributions indicate that the article should be sent, it is. If none do, it is not sent: The rules are used as a “logical or.” It is almost definitely a mistake to have a single feed that specifies distributions that start with an exclamation point along with some that don’t.

Distributions are text words, not patterns; it is usually a mistake to have entries like * or all there.

The flags parameter specifies miscellaneous parameters. They may be specified in any order; flags that take values should have the value immediately after the flag letter with no whitespace. The valid flags are

<code>< si ze</code>	An article will only be sent to the site if it is less than <code>si ze</code> bytes long. The default is no limit.
<code>A checks</code>	An article will only be sent to the site if it meets the requirements specified in the <code>checks</code> , which should be chosen from the following set: <ul style="list-style-type: none"> <code>d</code> Distribution header required <code>p</code> Do not check Path header before propagating.
<code>B hi gh/l ow</code>	If a site is being fed by a file, channel, or exploder, the server will usually start trying to write the information as soon as possible. Providing a buffer may give better system performance and help smooth out overall load if a large batch of news comes in. The value of the this flag should be two numbers separated by a slash. The first specifies the point at which the server can start draining the feed’s I/O buffer, and the second specifies when to stop writing and begin buffering again; the units are bytes. The default is to do no buffering, sending output as soon as it is possible to do so.
<code>F name</code>	This flag specifies the name of the file that should be used if it is necessary to begin spooling for the site. If <code>name</code> is not an absolute pathname, it is taken to be relative to <code>/news/spool/out.going</code> . Then, if the destination is a directory, the file to go in that directory will be used as filename.

G count	If this flag is specified, an article will only be sent to the site if it is posted to no more than <code>count</code> newsgroups.
H count	If this flag is specified, an article will only be sent to the site if it has <code>count</code> or fewer sites in its Path line. This flag should only be used as a rough guide because of the loose interpretation of the Path header; some sites put the poster's name in the header, and some sites that might logically be considered to be one hop become two because they put the posting workstation's name in the header. The default value for <code>count</code> is one.
I si ze	The flag specifies the size of the internal buffer for a file feed. If there are more file feeds than allowed by the system, they will be buffered internally in least recently used order. If the internal buffer grows bigger than <code>si ze</code> bytes, however, the data will be written out to the appropriate file.
N modi fers	The newsgroups that a site receives are modified according to the modifiers, which should be chosen from the following set: m Only moderated groups u Only unmoderated groups
S si ze	If the amount of data queued for the site gets to be larger than <code>si ze</code> bytes, then the server will switch to spooling, appending to a file specified by the F flag or <code>/news/spool/out.going/si tename</code> if the F flag is not specified. Spooling usually happens only for channel or exploder feeds.
T type	This flag specifies the type of feed for the site. <code>type</code> should be a letter chosen from the following set: c Channel f File l Log entry only m Funnel (multiple entries feed into one) p Program x Exploder. Each feed is described in the section on feed types. The default is <code>tf</code> .
W i tems	If a site is fed by file, channel, or exploder, this flag controls what information is written. If a site is fed by a program, only the asterisk (*) has any effect. The items should be chosen from the following set: b Size of the article in bytes. f Article's full pathname. g The newsgroup the article is in; if cross-posted, then the first of the groups this site gets. m Article's Message-ID. n Article's pathname relative to the spool directory. p The site that fed the article to the server; from the Path header. s The IP address of the site that sent the article. t Time article was received as seconds since epoch. * Names of the appropriate funnel entries; or all sites that get the article. D Value of the Distribution header; ? if none present. H All headers. N Value of the Newsgroups header. O Overview data. R Information needed for replication. More than one letter can be used; the entries will be separated by a space and written in the order in which they are specified. The default is <code>Wn</code> .

The `H` and `O` items are intended for use by programs that create news overview databases. If `H` is present, then the all the article's headers are written followed by a blank line. An `Xref` header (even if one does not appear in the filed article) and a `Bytes` header, specifying the article's size, will also be part of the headers. If used, this should be the only item in the list; if preceded by other items, however, a newline will be written before the headers. The `O` generates input to the `overchan(8)` program. It, too, should be the only item in the list.

The asterisk has special meaning. It expands to a space-separated list of all sites that received the current article. If the site is the target of a funnel, however (that is, it is named by other sites that have a `Tm` flag), then the asterisk expands to the names of the funnel feeds that received the article. If the site is fed by a program, then an asterisk in the `param` field will be expanded into the list of funnel feeds that received the article. A site fed by a program cannot get the site list unless it is the target of other `Tm` feeds.

The interpretation of the `param` field depends on the type of feed, and is explained in more detail in the section on feed types. It can be omitted.

The site named `ME` is special. There should only be one such entry, and it should be the first entry in the file. If the `ME` entry has a subscription list, then that list is automatically prepended to the subscription list of all other entries. For example, `*,!control,!junk,!foo.*` can be used to set up the initial subscription list for all feeds so that local postings are not propagated unless `foo.*` explicitly appears in the site's subscription list. Note that most subscriptions should have `!junk,!control` in their pattern list; see the discussion of control messages in `innd(8)`. (Unlike other news software, it does not affect what groups are received; that is done by the `active(5)` file.)

If the `ME` entry has a distribution subfield, then only articles that match the distribution list are accepted; all other articles are rejected. A commercial news server, for example, might have `!/local` to reject local postings from other, misconfigured, sites.

FEED TYPES

`innd` provides four basic types of feeds: `log`, `file`, `program`, and `channel`. An `exploder` is a special type of `channel`. In addition, several entries can feed into the same feed; these are funnel feeds, which refer to an entry that is one of the other types. Note that the term "feed" is technically a misnomer because the server does not transfer articles but reports that an article should be sent to the site.

The simplest feed is one that is fed by a `log` entry. Other than a mention in the news logfile, no data is ever written out. This is equivalent to a `Tf` entry writing to `/dev/null` except that no file is opened.

A site fed by a file is simplest type of feed. When the site should receive an article, one line is written to the file named by the `param` field. If `param` is not an absolute pathname, it is taken to be relative to `/news/spool/out.going`. If empty, the filename defaults to `/news/spool/out.going/sitename`. This name should be unique.

When a site fed by a file is flushed (see `ctlinnd`), the following steps are performed. The script doing the flush should have first renamed the file. The server tries to write out any buffered data and then closes the file. The renamed file is now available for use. The server will then reopen the original file, which will now get created.

A site fed by a program has a process spawned for every article that the site receives. The `param` field must be a `sprintf(3)` format string that may have a single `%s` parameter, which will be given a pathname for the article, relative to the news spool directory. The full pathname may be obtained by prefixing the `%s` in the `param` field by the news spool directory prefix. Standard input will be set to the article or `/dev/null` if the article cannot be opened for some reason. Standard output and error will be set to the error log. The process will run with the user and group ID of the `/news/lib/innd` directory. `innd` will try to avoid spawning a shell if the command has no shell meta-characters; this feature can be defeated by appending a semicolon to the end of the command. The full pathname of the program to be run must be specified; for security, `PATH` is not searched.

If the entry is the target of a funnel, and if the `w*` flag is used, then a single asterisk may be used in the `param` field where it will be replaced by the names of the sites that fed into the funnel. If the entry is not a funnel, or if the `w*` flag is not used, then the asterisk has no special meaning.

Flushing a site fed by a program does no action.

When a site is fed by a channel or exploder, the `param` field names the process to start. Again, the full pathname of the process must be given. When the site is to receive an article, the process receives a line on its standard input telling it about the article. Standard output and error and the user and group ID of the all subprocess are set as for a program feed. If the process exits, it will be restarted. If the process cannot be started, the server will spool input to a file named `/news/spool/out.going/si tename`. It will then try to start the process some time later.

When a site fed by a channel or exploder is flushed, the server closes down its end of the pipe. Any pending data that has not been written will be spooled; see the description of the `s` flag. No signal is sent; it is up to the program to notice EOF on its standard input and exit. The server then starts a new process.

Exploders are a superset of channel feeds. In addition to channel behavior, exploders can be sent command lines. These lines start with an exclamation point, and their interpretation is up to the exploder. The following messages are generated automatically by the server:

```
newgroup group
rmgroup group
flush
flush site
```

These messages are sent when the `ctlinn` command of the same name is received by the server. In addition, the `send` command can be used to send an arbitrary command line to the exploder child-process. The primary exploder is `buffchan(8)`.

Funnel feeds provide a way of merging several site entries into a single output stream. For a site feeding into a funnel, the `param` field names the actual entry that does the feeding.

For more details on setting up different types of news feeds, see the INN installation manual.

EXAMPLES

```
## Initial subscription list and our distributions.
ME:*;!junk,!foo.*@world,usa,na,ne,foo,ddn,gnu,inet\
::
## Feed all moderated source postings to an archiver
source-archive:!.*,comp.sources.*\
:Tp,Nm:/usr/local/bin/archive %s
## Watch for big postings
watcher!*\
:Tc,Wbnm\
:exec awk '$1 > 1000000 { print "BIG", $2, $3 }' >/dev/console
## A UUCP feed, where we try to keep the "batching" between 4 and 1K.
ihnp4:/world,usa,na,ddn,gnu\
:Tf,Wfb,B4096/1024:
## Usenet as mail; note ! in funnel name to avoid Path conflicts.
## Can't use ! in "fred" since it would like look a UUCP address.
fred!*;comp.sources.unix,comp.sources.bugs\
:Tm:mailer!
barney@bar.com:!*;news.software.nntp,comp.sources.bugs\
:Tm:mailer!
mailer!*!\
:W*,Tp:/usr/ucb/Mail -s "News article" *
## NNTP feeds fed off-line via nntpsend or equivalent.
feed1::Tf,Wnm:feed1.domain.name
peer.foo.com:foo.*:Tf,Wnm:peer.foo.com
## Real-time transmission.
mit.edu:/world,usa,na,ne,ddn,gnu,inet\
:Tc,Wnm:/nntplink -i stdin mit.edu
## Two sites feeding into a hypothetical NNTP fan-out program:
nic.near.net:\
:Tm:nntpfunnel1
```

```

uunet.uu.net/uunet: !ne.* /world,usa,na,foo,ddn,gnu,inet\
:Tm:nntpfunnel1
nntpfunnel1: !*\
:Tc,Wmn*/nntpfanout
## A UUCP site that wants comp.* and moderated soc groups
uucpsite!comp: !*,comp.* /world,usa,na,gnu\
:Tm:uucpsite
uucpsite!soc: !*,soc.* /world,usa,na,gnu\
:Tm,Nm:uucpsite
uucpsite: !*\
:Tf,Wfb:/usr/spool/batch/uucpsite

```

The last two sets of entries show how funnel feeds can be used. For example, the nntpfanout program would receive lines like the following on its standard input:

```

<123@litchi.foo.com> comp/sources/unix/888 nic.near.net uunet.uu.net
<124@litchi.foo.com> ne/general/1003 nic.near.net

```

Because the UUCP funnel is only destined for one site, the asterisk is not needed and entries like the following will be written into the file:

```

<qwe#37x@snark.uu.net>comp/society/folklore/3
<123@litchi.foo.com> comp/sources/unix/888

```

newslog

newslog—Description of Usenet log files.

DESCRIPTION

Most log files created by Usenet programs reside in the `/var/log/news` directory and have a `.log` extension. Several versions are usually kept with an additional extension such as `.1`, `.2`, and so on; the higher the number, the older the log. The older versions are compressed.

The `scanlogs` script and related utilities (see `newslog(8)`) are responsible for rotating and compressing these files.

Some log files always have data, others only have data if there is a problem, and others are only created if a particular program is used or configuration parameter is set. The `innstat` script (see `newslog(8)`) monitors the size of all log files.

The following files will only accumulate data under the direction of `control.ct1(5)`:

`control.log`, `miscctl.log`, `newgroup.log`, `rmgroup.log`, `unwanted.log`

In order to create these files, the `message` and `action` fields of `control.ct1` should be chosen from the following table:

<i>Message</i>	<i>Action</i>	<i>Meaning</i>
all	log=miscctl	Log all messages by default
default	log=miscctl	Log unknown messages
newgroup	doit=newgroup	Create group and log message
newgroup	log=newgroup	Log message

continues

<i>Message</i>	<i>Action</i>	<i>Meaning</i>
rmgroup	doit=rmgroup	Remove group and log message
rmgroup	log=rmgroup	Log message
“other”	doit=miscctl	Log and process the message
“other”	log=miscctl	Log message

Here, “other” refers to any other control message such as:

```
checkgroups ihave sendme sendsys senduuname version
```

The following is a list of log files.

control.log	This file maintains a count of the number of newgroup and rmgroup control messages seen for each newsgroup. The count is of the number of control messages with identical arguments, regardless of whether they were actually processed. All control arguments, including invalid ones, are counted. This file is updated by tally.control, which is invoked by scanlogs if either the newgroup or rmgroup logs exist. This file is not rotated.
errlog	This file contains the standard output and standard error of any program spawned by innd(8). The most common programs are the control-message handlers found in /news/bin/control. This file should be empty. Scanlogs will print the entire contents of this log file if it is non-empty.
expire.log	By default, when news.daily is going to expire old news articles, it writes the date to this file, followed by any output from expire(8) and the ending date. All lines but the first are indented four spaces.
miscctl.log	When control.ct1 is configured as described above, all control messages except newgroup and rmgroup are appended to this file by writelog. There will be a summary line describing the message and the action taken, followed by the article indented by four spaces and a blank line.
newgroup.log	When control.ct1 is configured as described above, all newgroup messages are appended to this file using the same format as for miscctl.log.
news	This file logs articles received by innd. scanlogs summarizes the rejected articles reported in this file.
news.crit	All critical error messages issued by innd are appended to this file via syslog(3). This log file should be empty. scanlogs will print the entire contents of this log file if it is non-empty. You should have the following line in your syslog.conf(5) file: news.crit /var/log/news/news.crit
news.err	All major error messages issued by innd are appended to this file via syslog. This log file should be empty. scanlogs will print the entire contents of this log file if it is non-empty. You should have the following line in your syslog.conf file: news.err /var/log/news/news.err
news.notice	All standard error messages and status messages issued by innd are appended to this file via syslog. scanlogs uses the awk(1) script innlog.awk to summarize this file. You should have the following line in your syslog.conf file: news.notice /var/log/news/news.notice
nntpsend.log	The nntpsend(8) programs appends all status messages to this file.
rmgroup.log	When control.ct1 is configured as described previously, all rmgroup messages are appended to this file using the same format as for miscctl.log.
unwanted.log	This log maintains a count of the number of articles that were rejected because they were posted to newsgroups that do not exist at the local site. This file is updated by tally.unwanted and maintained in reverse numeric order (the most popular rejected group first). This file is not rotated.

nfs

nfs—NFS `fstab` format and options.

SYNOPSIS

```
/etc/fstab
```

DESCRIPTION

The `fstab` file contains information about which filesystems to mount where and with what options. For NFS mounts, it contains the server name and exported server directory to mount from, the local directory that is the mount point, and the NFS-specific options that control the way the filesystem is mounted. Here is an example from an `/etc/fstab` file from an NFS mount.

```
server:/usr/local/pub /pub nfs rsize=8192,wsz=8192,timeo=14,intr
```

OPTIONS

<code>rsize=n</code>	The number of bytes NFS uses when reading files from an NFS server. The default value is dependent on the kernel, currently 1024 bytes. (However, throughput is improved greatly by asking for <code>rsize=8192</code> .)
<code>wsz=n</code>	The number of bytes NFS uses when writing files to an NFS server. The default value is dependent on the kernel, currently 1024 bytes. (However, throughput is improved greatly by asking for <code>wsz=8192</code> .)
<code>timeo=n</code>	The value in tenths of a second before sending the first retransmission after an RPC time-out. The default value is 7 tenths of a second. After the first time-out, the time-out is doubled after each successive time-out until a maximum time-out of 60 seconds is reached or the enough retransmissions have occurred to cause a major time-out. Then, if the filesystem is hard mounted, each new time-out cascade restarts at twice the initial value of the previous cascade, again doubling at each retransmission. The maximum time-out is always 60 seconds. Better overall performance may be achieved by increasing the time-out when mounting on a busy network, to a slow server, or through several routers or gateways.
<code>retrans=n</code>	The number of minor time-outs and retransmissions that must occur before a major time-out occurs. The default is 3 time-outs. When a major time-out occurs, the file operation is either aborted or a “server not responding” message is printed on the console.
<code>acregmin=n</code>	The minimum time in seconds that attributes of a regular file should be cached before requesting fresh information from a server. The default is 3 seconds.
<code>acregmax=n</code>	The maximum time in seconds that attributes of a regular file can be cached before requesting fresh information from a server. The default is 60 seconds.
<code>acdirmin=n</code>	The minimum time in seconds that attributes of a directory should be cached before requesting fresh information from a server. The default is 30 seconds.
<code>acdirmax=n</code>	The maximum time in seconds that attributes of a directory can be cached before requesting fresh information from a server. The default is 60 seconds.
<code>actimeo=n</code>	Using <code>actimeo</code> sets all of <code>acregmin</code> , <code>acregmax</code> , <code>acdirmin</code> , and <code>acdirmax</code> to the same value. There is no default value.

<code>retry=n</code>	The number of times to retry a backgrounded NFS mount operation before giving up. The default value is 10000 times.
<code>namlen=n</code>	When an NFS server does not support version 2 of the RPC mount protocol, this option can be used to specify the maximum length of a filename that is supported on the remote filesystem. This is used to support the POSIX <code>pathconf</code> functions. The default is 255 characters.
<code>port=n</code>	The numeric value of the port to connect to the NFS server on. If the port number is 0 (the default) then query the remote host's port mapper for the port number to use. If the remote host's NFS daemon is not registered with its port mapper, the standard NFS port number 2049 is used instead.
<code>mountport=n</code>	The numeric value of the <code>mountd</code> port.
<code>mounthost=name</code>	The name of the host running <code>mountd</code> .
<code>mountprog=n</code>	Use an alternate RPC program number to contact the mount daemon on the remote host. This option is useful for hosts that can run multiple NFS servers. The default value is 100005, which is the standard RPC mount daemon program number.
<code>mountvers=n</code>	Use an alternate RPC version number to contact the mount daemon on the remote host. This option is useful for hosts that can run multiple NFS servers. The default value is version 1.
<code>nfsprog=n</code>	Use an alternate RPC program number to contact the NFS daemon on the remote host. This option is useful for hosts that can run multiple NFS servers. The default value is 100003, which is the standard RPC NFS daemon program number.
<code>nfsvers=n</code>	Use an alternate RPC version number to contact the NFS daemon on the remote host. This option is useful for hosts that can run multiple NFS servers. The default value is version 2.
<code>bg</code>	If the first NFS mount attempt times out, continue trying the mount in the background. The default is to not to background the mount on time-out but to fail.
<code>fg</code>	If the first NFS mount attempt times out, fail immediately. This is the default.
<code>soft</code>	If an NFS file operation has a major time-out, then report an I/O error to the calling program. The default is to continue retrying NFS file operations indefinitely.
<code>hard</code>	If an NFS file operation has a major time-out, then report "server not responding" on the console and continue retrying indefinitely. This is the default.
<code>intr</code>	If an NFS file operation has a major time-out and it is hard mounted, then allow signals to interrupt the file operation and cause it to return <code>EINTR</code> to the calling program. The default is to not allow file operations to be interrupted.
<code>posix</code>	Mount the NFS filesystem using POSIX semantics. This allows an NFS filesystem to properly support the POSIX <code>pathconf</code> command by querying the mount server for the maximum length of a filename. To do this, the remote host must support version 2 of the RPC mount protocol. Many NFS servers support only version 1.
<code>nocto</code>	Suppress the retrieval of new attributes when creating a file.
<code>noac</code>	Disable all forms of attribute caching entirely. This extracts a server performance penalty, but it allows two different NFS clients to get reasonably good results when both clients are actively writing to a common filesystem on the server.
<code>tcp</code>	Mount the NFS filesystem using the TCP protocol instead of the default UDP protocol. Many NFS servers only support UDP.
<code>udp</code>	Mount the NFS filesystem using the UDP protocol. This is the default. All the non-value options have corresponding <code>nooption</code> forms. For example, <code>nointr</code> means don't allow file operations to be interrupted.

FILES

`/etc/fstab`

AUTHOR

Rick Sladkey (`jrs@world.std.com`)

BUGS

The `bg`, `fg`, `retry`, `posix`, and `nocto` options are parsed by `mount` but currently are silently ignored. The `tcp` and `namlen` options are implemented but are not currently supported by the Linux kernel. The `umount` command should notify the server when an NFS filesystem is unmounted.

Linux 0.99, 20 November 1993

nnrp.access

`nnrp.access`—Access file for on-campus NNTP sites.

DESCRIPTION

The file `/news/lib/nnrp.access` specifies the access control for those NNTP sites that are not handled by the main InterNetNews daemon `inn(8)`. The `nnrpd(8)` server reads it when first spawned by `inn`.

Comments begin with a number sign (`#`) and continue through the end of the line. Blank lines and comments are ignored. All other lines should consist of five fields separated by colons:

```
hosts:perms:username:password:patterns
```

The first field is a `wildmat(3)`-style pattern specifying the names or Internet address of a set of hosts. Before a match is checked, the client's hostname (or its Internet address if `gethostbyaddr(3)` fails) is converted to lowercase. Each line is matched in turn, and the last successful match is taken as the correct one.

The second field is a set of letters specifying the permissions granted to the client. The `perms` should be chosen from the following set:

R	The client can retrieve articles
P	The client can post articles

The third and fourth fields specify the `username` and `password` that the client must use to authenticate themselves before the server will accept any articles. Note that no authentication (other than a matching entry in this file) is required for newsreading. If they are empty, then no password is required. Whitespace in these fields will result in the client being unable to properly authenticate themselves and may be used to disable access.

The fifth field is a set of patterns identifying the newsgroups that the client is allowed to access. The `patterns` are interpreted in the same manner as the `newsfeeds(5)` file. The default, however, denies access to all groups.

The access file is normally used to provide host-level access control for reading and posting articles. There are times, however, when this is not sufficient and user-level access control is needed. Whenever an NNTP `authinfo` command is used, the `nnrpd` server rereads this file and looks for a matching username and password. If the local newsreaders are modified to send the `authinfo` command, then all host entries can have no access and specific users can be granted the appropriate read and post access. For example:

```
## host:perm:user:pass:groups
## Default is no access.
:: -no- : -no- :!*
## F00 hosts have no password, can read anything.
.foo.com:Read Post:::*
## A related workstation can't access F00 newsgroups.
lenox.foo.net:RP:martha:hiatt:*,!foo.*
```

If the file contains passwords, it should not be world-readable.

nntpsend.ctl

`nntpsend.ctl`—List of sites to feed via `nntpsend`.

DESCRIPTION

The file `/news/lib/nntpsend.ctl` specifies the default list of sites to be fed by `nntpsend(8)`.

Comments begin with a number sign (`#`) and continue through the end of the line. Blank lines and comments are ignored. All other lines should consist of four fields separated by a colon.

The first field is the name of the site as specified in the `newsfeeds(5)` file.

The second field should be the hostname or IP address of the remote site.

The third field, if non-empty, specifies the default tail truncation size of site's batchfile. This is passed to `shrinkfile` as the `-s` flag. If this field is empty, no truncation is performed.

The fourth field specifies some default flags passed to `innxmit(8)`. The flag `-a` is always given to `innxmit` and need not appear here. If no `-t` timeout flag is given in this field and on the `nntpsend` command line, `-t 180` will be given to `innxmit`.

overview.fmt

`overview.fmt`—Format of news overview database.

DESCRIPTION

The file `/news/lib/overview.fmt` specifies the organization of the news overview database. Blank lines and lines beginning with a number sign (#) are ignored. The order of lines in this file is important; it determines the order in which the fields will appear in the database.

Most lines will consist of an article header name, optionally followed by a colon. A trailing set of lines can have the word `full` appear after the colon; this indicates that the header should appear as well as its value.

If this file is changed, it is usually necessary to rebuild the existing overview database using `expireover(8)` after removing all existing overview files.

The default file, show here, is compatible with Geoff Collyer's `nov` package:

```
Subject:
From:
Date:
Message-ID:
References:
Bytes:
Lines:
## Some newsreaders get better performance if Xref is present
#Xref:full
```

HISTORY

Written by Rich Salz (`rsalz@uunet.uu.net`) for InterNetNews. Intended to be compatible with the `nov` package written by Geoff Collyer (`geoff@world.std.com`).

passwd

passwd—Password file.

DESCRIPTION

`passwd` is an ASCII file that contains a list of the system's users and the passwords they must use for access. The password file should have general read permission (many utilities, such as `ls(1)`, use it to map user IDs to usernames) but write access only for the superuser.

In the good old days, there was no great problem with this general read permission. Everybody could read the encrypted passwords, but the hardware was too slow to crack a well-chosen password, and moreover, the basic assumption used to be that of a friendly user community. These days, many people run some version of the shadow password suite, where `/etc/passwd` has *s instead of passwords, and the encrypted passwords are in `/etc/shadow`, which is readable by root only.

When you create a new login, leave the password field empty and use `passwd(1)` to fill it. A star (*) in the password field means that this user cannot log in via `login(1)`.

There is one entry per line, and each line has the format:

```
login_name:passwd:UID:GID:user_name:directory:shell
```

The field descriptions are

<code>login_name</code>	The name of the user on the system.
<code>password</code>	The encrypted optional user password.
<code>UID</code>	The numerical user ID.
<code>GID</code>	The numerical group ID for this user.
<code>user_name</code>	The (optional) comment field (often a full username).
<code>directory</code>	The user's <code>\$HOME</code> directory.
<code>shell</code>	The program to run at login (if empty, use <code>/bin/sh</code>).

NOTE

If your root file system is on `/dev/ram`, you must save a changed password file to your root filesystem floppy before you shut down the system and check the access rights. If you want to create user groups, their GIDs must be equal and there must be an entry in `/etc/group`, or no group will exist.

FILES

`/etc/passwd`

passwd.nntp

`passwd.nntp`—Passwords for connecting to remote NNTP servers.

DESCRIPTION

The file `/news/lib/passwd.nntp` contains host-name-password triplets for use when authenticating client programs to NNTP servers. This file is normally interpreted by the `NNTPsend-password` routine in `libinn(3)`. Blank lines and lines beginning with a number sign (`#`) are ignored. All other lines should consist of three or fields separated by colons:

```
host:name:password
host:name:password:style
```

The first field is the name of a host and is matched in a case-insensitive manner. The second field is a username, and the third is a password. The optional fourth field specifies the type of authentication to use. The default is `authinfo`, which means that NNTP `authinfo` commands are used to authenticate to the remote host. If either the username or password are empty, then the related command will not be sent. (The `authinfo` command is a common extension to RFC 977.) For example:

```
## UUNET needs a password, MIT doesn't.
mit.edu:bbn::authinfo
uunet.uu.net:bbn:yoyoma:authinfo
```

This file should not be world-readable.

pbm

`pbm`—Portable bitmap file format.

DESCRIPTION

The portable bitmap format is a lowest common denominator monochrome file format. It was originally designed to make it reasonable to mail bitmaps between different types of machines using the typical stupid network mailers we have today. Now it serves as the common language of a large family of bitmap conversion filters. The definition is as follows:

A “magic number” for identifying the file type. A `pbm` file’s magic number is the two characters `P1`.

Whitespace (blanks, Tabs, CRs, LFs).

A width, formatted as ASCII characters in decimal.

Whitespace.

A height, again in ASCII decimal.

Whitespace.

Width * height bits, each either 1 or 0, starting at the top-left corner of the bitmap, proceeding in normal English reading order.

The character 1 means black; 0 means white.

Whitespace in the bits section is ignored.

Characters from a # to the next end-of-line are ignored (comments).

No line should be longer than 70 characters.

Here is an example of a small bitmap in this format:

```
P1
# feep.pbm
24 7
0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
0 1 1 1 1 0 0 1 1 1 1 0 0 1 1 1 1 0 0 1 1 1 1 0
0 1 0 0 0 0 0 1 0 0 0 0 0 1 0 0 0 0 0 1 0 0 1 0
0 1 1 1 0 0 0 1 1 1 0 0 0 1 1 1 0 0 0 1 1 1 1 0
0 1 0 0 0 0 0 1 0 0 0 0 0 1 0 0 0 0 0 1 0 0 0 0
0 1 0 0 0 0 0 1 1 1 1 0 0 1 1 1 1 0 0 1 0 0 0 0
0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
```

Programs that read this format should be as lenient as possible, accepting anything that looks remotely like a bitmap.

There is also a variant on the format, available by setting the RAWBITS option at compile time. This variant is different in the following ways:

The “magic number” is P4 instead of P1.

The bits are stored eight per byte, high bit first and low bit last.

No whitespace is allowed in the bits section, and only a single character of whitespace (typically a newline) is allowed after the height.

The files are eight times smaller and many times faster to read and write.

pgm

pgm—Portable graymap file format.

DESCRIPTION

The portable graymap format is a lowest common denominator grayscale file format. The definition is as follows:

A “magic number” for identifying the file type. A `pgm` file’s magic number is the two characters `P2`.

Whitespace (blanks, Tabs, CRs, LFs).

A width, formatted as ASCII characters in decimal.

Whitespace.

A height, again in ASCII decimal.

Whitespace.

The maximum gray value, again in ASCII decimal.

Whitespace.

Width * height gray values, each in ASCII decimal, between 0 and the specified maximum value, separated by whitespace, starting at the top-left corner of the graymap, proceeding in normal English reading order. A value of 0 means black, and the maximum value means white.

Characters from a `#` to the next end-of-line are ignored (comments).

No line should be longer than 70 characters.

Here is an example of a small graymap in this format:

```
P2
# feep.pgm
24 7
15
0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
0 3 3 3 3 0 0 7 7 7 7 0 0 11 11 1111 0 0 15 1515 15 0
0 3 0 0 0 0 0 7 0 0 0 0 0 11 0 0 0 0 0 15 0 0 150
0 3 3 3 0 0 0 7 7 7 0 0 0 11 11 110 0 0 15 15 15 150
0 3 0 0 0 0 0 7 0 0 0 0 0 11 0 0 0 0 0 15 0 0 0 0
0 3 0 0 0 0 0 7 7 7 7 0 0 11 11 1111 0 0 15 0 0 0 0
0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0
```

Programs that read this format should be as lenient as possible, accepting anything that looks remotely like a graymap.

There is also a variant on the format, available by setting the `RAWBITS` option at compile time. This variant is different in the following ways:

The “magic number” is `P5` instead of `P2`.

The gray values are stored as plain bytes, instead of ASCII decimal.

No whitespace is allowed in the `grays` section, and only a single character of whitespace (typically a newline) is allowed after the `maxval`.

The files are smaller and many times faster to read and write.

Note that this raw format can only be used for `maxvals` less than or equal to 255. If you use the `pgm` library and try to write a file with a larger `maxval`, it will automatically fall back on the slower but more general plain format.

ppm

ppm—Portable pixmap file format.

DESCRIPTION

The portable pixmap format is a lowest common denominator color image file format. The definition is as follows:

A “magic number” for identifying the file type. A ppm file’s magic number is the two characters P3.

Whitespace (blanks, Tabs, CRs, LFs).

A width, formatted as ASCII characters in decimal.

Whitespace.

A height, again in ASCII decimal.

Whitespace.

The maximum color-component value, again in ASCII decimal.

Whitespace.

Width * height pixels, each three ASCII decimal values between 0 and the specified maximum value, starting at the top-left corner of the pixmap, proceeding in normal English reading order. The three values for each pixel represent red, green, and blue; a value of 0 means that color is off, and the maximum value means that color is maxed out.

Characters from a # to the next end-of-line are ignored (comments).

No line should be longer than 70 characters.

Here is an example of a small pixmap in this format:

```
P3
# feep.ppm
4 4
15
0 0 0 0 0 0 0 0 15 0 15
0 0 0 0 15 7 0 0 0 0 0 0
0 0 0 0 0 0 0 0 15 7 0 0 0
15 0 15 0 0 0 0 0 0 0 0
```

Programs that read this format should be as lenient as possible, accepting anything that looks remotely like a pixmap.

There is also a variant on the format, available by setting the `RAWBITS` option at compile time. This variant is different in the following ways:

The “magic number” is `P6` instead of `P3`.

The pixel values are stored as plain bytes, instead of ASCII decimal.

Whitespace is not allowed in the pixels area, and only a single character of whitespace (typically a newline) is allowed after the `maxval`.

The files are smaller and many times faster to read and write.

Note that this raw format can only be used for `maxvals` less than or equal to 255. If you use the `ppm` library and try to write a file with a larger `maxval`, it will automatically fall back on the slower but more general plain format.

/proc

`/proc`—Process information pseudo-filesystem.

DESCRIPTION

`/proc` is a pseudo-filesystem that is used as an interface to kernel data structures rather than reading and interpreting `/dev/kmem`. Most of it is read-only, but some files allow kernel variables to be changed.

The following outline gives a quick tour through the `/proc` hierarchy.

<code>[number]</code>	There is a numerical subdirectory for each running process; the subdirectory is named by the process ID. Each contains the following pseudo-files and directories.
<code>cmdline</code>	This holds the complete command line for the process, unless the whole process has been swapped out or unless the process is a zombie. In either of these later cases, there is nothing in this file: That is, a read on this file will return as having read 0 characters. This file is null-terminated but not newline-terminated.
<code>cwd</code>	This is a link current working directory of the process. To find out the <code>cwd</code> of process 20, for instance, you can do this: <code>cd /proc/20/cwd; /bin/pwd</code> . Note that the <code>pwd</code> command is often a shell built in and might not work properly in this context.
<code>environ</code>	This file contains the environment for the process. The entries are separated by null characters, and there may be a null character at the end. Thus, to print out the environment of process 1, you would do <pre>(cat /proc/1/environ; echo) tr "\000" "\n"</pre> For a reason why one should want to do this, see <code>lilo(8)</code> .
<code>exe</code>	A pointer to the binary that was executed and appears as a symbolic link. <code>readlink(2)</code> on the <code>exe</code> special file returns a string in the format: <pre>[device]:inode</pre> For example, <code>[0301]:1502</code> is inode 1502 on device major 03 (IDE, MFM, and so on drives), minor

01 (first partition on the first drive). Also, the symbolic link can be dereferenced normally; attempting to open `exe` will open the executable. You can even type `/proc/[number]/exe` to run another copy of the same process as `[number]`.

`find(1)` with the `-inum` option can be used to locate the file.

fd

This is a subdirectory containing one entry for each file that the process has open, named by its file descriptor, and that is a symbolic link to the actual file (as the `exe` entry does). Thus, 0 is standard input, 1 standard output, 2 standard error, and so on.

Programs that will take a filename but will not take the standard input and that write to a file but will not send their output to standard output can be effectively foiled this way, assuming that `-i` is the flag designating an input file and `-o` is the flag designating an output file:

```
foobar -i /proc/self/fd/0 -o /proc/self/fd/1 ...
```

and you have a working filter. Note that this will not work for programs that seek on their files because the files in the `fd` directory are not seekable.

`/proc/self/fd/N` is approximately the same as `/dev/fd/N` in some UNIX and UNIX-like systems. Most Linux MAKEDEV scripts symbolically link `/dev/fd` to `/proc/self/fd`, in fact.

maps

A file containing the currently mapped memory regions and their access permissions.

The format is

address	perms	offset	dev	i node
00000000-0002f000	r-x-	0000400	03:03	1401
0002f000-00032000	rw-x-p	0002f400	03:03	1401
00032000-0005b000	rw-x-p	00000000	00:00	0
60000000-60098000	rw-x-p	00000400	03:03	215
60098000-600c7000	rw-x-p	00000000	00:00	0
bfffa000-c0000000	rw-x-p	00000000	00:00	0

`address` is the address space in the process that it occupies. `perms` is a set of permissions: `r` = read, `w` = write, `x` = execute, `s` = shared, `p` = private (copy on write).

`offset` is the offset into the `file/whatever`, `dev` is the device (major: minor), and `i node` is the inode on that device. `0` indicates that no inode is associated with the memory region, as the case would be with `bss`.

mem

This is not the same as the `mem` (1,1) device, despite the fact that it has the same device numbers.

The `/dev/mem` device is the physical memory before any address translation is done, but the `mem` file here is the memory of the process that accesses it. This cannot be `mmap(2)`ed currently, and will not be until a general `mmap(2)` is added to the kernel. (This might have happened by the time you read this.)

mmap

Directory of maps by `mmap(2)` that are symbolic links such as `exe`, `fd/*`, and so on. Note that maps includes a superset of this information, so `/proc/*/mmap` should be considered obsolete.

`0` is usually `libc.so.4`.

`/proc/*/mmap` was removed in Linux kernel version 1.1.40. (It really was obsolete!)

root

UNIX and Linux support the idea of a per-process root of the filesystem, set by the `chroot(2)` system call. `root` points to the filesystem root and behaves as `exe`, `fd/*`, and so on do.

stat

Status information about the process. This is used by `ps(1)`. The fields, in order, with their proper `scanf(3)` format specifiers, are

`pid %d` The process ID.

`comm %s` The filename of the executable in parentheses. This is visible whether or not the executable is swapped out.

state %c	One character from the string <code>RSDZT</code> where <code>R</code> is running, <code>S</code> is sleeping in an interruptible wait, <code>D</code> is sleeping in an uninterruptible wait or swapping, <code>Z</code> is zombie, and <code>T</code> is traced or stopped (on a signal).
ppid %d	The PID of the parent.
pgrp %d	The process group ID of the process.
session %d	The session ID of the process.
tty %d	The <code>tty</code> the process uses.
tpgid %d	The process group ID of the process that currently owns the <code>tty</code> that the process is connected to.
flags %u	The flags of the process. Currently, every flag has the math bit set because <code>cr0.s</code> checks for math emulation, so this is not included in the output. This is probably a bug because not every process is a compiled C program. The math bit should be a decimal 4, and the traced bit is decimal 10.
minflt %u	The number of minor faults the process has made, those that have not required loading a memory page from disk.
cmiflt %u	The number of minor faults that the process and its children have made.
majflt %u	The number of major faults the process has made, those that have required loading a memory page from disk.
cmajflt %u	The number of major faults that the process and its children have made.
utime %d	The number of jiffies that this process has been scheduled in user mode.
stime %d	The number of jiffies that this process has been scheduled in kernel mode.
cutime %d	The number of jiffies that this process and its children have been scheduled in user mode.
cstime %d	The number of jiffies that this process and its children have been scheduled in kernel mode.
counter %d	The current maximum size in jiffies of the process's next timeslice, or what is currently left of its current timeslice if it is the currently running process.
priority %d	The standard nice value, plus fifteen. The value is never negative in the kernel.
timeout %u	The time in jiffies of the process's next time-out.
itrealvalue %u	The time (in jiffies) before the next <code>SIGALRM</code> is sent to the process due to an interval timer.
starttime %d	Time the process started in jiffies after system boot.
vsize %u	Virtual memory size.
rss %u	Resident set size: Number of pages the process has in real memory, minus 3 for administrative purposes. This is just the pages that count toward text, data, or stack space. This does not include pages that have not been demand-loaded in or that are swapped out.
rlim %u	Current limit in bytes on the <code>rss</code> of the process (usually 2,147,483,647).
startcode %u	The address above which program text can run.
endcode %u	The address below which program text can run.
startstack %u	The address of the start of the stack.
kstkesp %u	The current value of <code>esp</code> (32-bit stack pointer), as found in the kernel stack page for the process.
kstkeip %u	The current EIP (32-bit instruction pointer).
signal %d	The bitmap of pending signals (usually 0).
blocked %d	The bitmap of blocked signals (usually 0, 2 for shells).

sigignore %d	The bitmap of ignored signals.
sigcatch %d	The bitmap of caught signals.
wchan %u	This is the "channel" in which the process is waiting. This is the address of a system call and can be looked up in a name list if you need a textual name. (If you have an up-to-date <code>/etc/psdatabase</code> , then try <code>ps -l</code> to see the <code>WCHAN</code> field in action.)
cpuinfo	This is a collection of CPU and system architecture dependent items; for each supported architecture is a different list. The only two common entries are <code>cpu</code> , which is the CPU currently in use, and <code>BogoMIPS</code> , a system constant that is calculated during kernel initialization.
devices	Text listing of major numbers and device groups. This can be used by <code>MAKEDEV</code> scripts for consistency with the kernel.
dma	This is a list of the registered ISA DMA (direct memory access) channels in use.
filesystems	A text listing of the filesystems that were compiled into the kernel. Incidentally, this is used by <code>mount(1)</code> to cycle through different filesystems when none is specified.
interrupts	This is used to record the number of interrupts per each IRQ on (at least) the i386 architecture. Very easy to read formatting done in ASCII.
ioports	This is a list of currently registered input-output port regions that are in use.
kcore	This file represents the physical memory of the system and is stored in the core file format. With this pseudo-file and an unstripped kernel (<code>/usr/src/linux/tools/zSystem</code>) binary, GDB can be used to examine the current state of any kernel data structures. The total length of the file is the size of physical memory (RAM) plus 4KB.
kmsg	This file can be used instead of the <code>syslog(2)</code> system call to log kernel messages. A process must have superuser privileges to read this file, and only one process should read this file. This file should not be read if a <code>syslog</code> process is running that uses the <code>syslog(2)</code> system call facility to log kernel messages. Information in this file is retrieved with the <code>dmesg(8)</code> program.
ksyms	This holds the kernel exported symbol definitions used by the <code>modules(X)</code> tools to dynamically link and bind loadable modules.
loadavg	The load average numbers give the number of jobs in the run queue averaged over 1, 5, and 15 minutes. They are the same as the load average numbers given by <code>uptime(1)</code> and other programs.
malloc	This file is only present if <code>CONFIGDEBUGMALLOC</code> was defined during compilation.
meminfo	This is used by <code>free(1)</code> to report the amount of free and used memory (both physical and swap) on the system as well as the shared memory and buffers used by the kernel. It is in the same format as <code>free(1)</code> except in bytes rather than KB.
modules	A text list of the modules that have been loaded by the system.
net	Various net pseudo-files, all of which give the status of some part of the networking layer. These files contain ASCII structures and are therefore readable with <code>cat</code> . However, the standard <code>netstat(8)</code> suite provides much cleaner access to these files.
arp	This holds an ASCII readable dump of the kernel ARP table used for address resolutions. It will show both dynamically learned and pre-programmed ARP entries. The format is

IP address	HW type	Flags	HW address
10.11.100.129	0x1	0x6	00:20:8A:00:0C:5A
10.11.100.5	0x1	0x2	00:C0:EA:00:00:4E
44.131.10.6	0x3	0x2	GW4PTS

IP address is the IPv4 address of the machine. The HW type is the hardware type of the address from RFC 826. The flags are the internal flags of the ARP structure (as defined in `/usr/include/linux/if_arp.h`) and the HW address is the physical layer mapping for that IP address if it is known.

dev The dev pseudo-file contains network device status information. This gives the number of received and sent packets, the number of errors and collisions, and other basic statistics. These are used by the `ifconfig(8)` program to report device status. The format is

```
Inter-| Receive          | Transmit
face | packets errs drop fifo frame|packets errs drop fifo colls carrier

lo:   0      0    0    0    0    2353    0    0    0    0    0

eth0: 644324 1    0    0    1    563770 0    0    0    581    0
```

ipx No information.

ipx_route No information.

rarp This file uses the same format as the ARP file and contains the current reverse mapping database used to provide `rarp(8)` reverse address lookup services. If `rarp` is not configured into the kernel, this file will not be present.

raw Holds a dump of the RAW socket table. Much of the information is not of use apart from debugging. The `s1` value is the kernel hash slot for the socket; the `local_address` is the local address and protocol number pair. `st` is the internal status of the socket. The `tx_queue` and `rx_queue` are the outgoing and incoming data queue in terms of kernel memory usage. The `tr`, `tm->when`, and `rexmits` fields are not used by RAW. The `uid` field holds the creator euid of the socket.

route No information but looks similar to `route(8)`.

snmp This file holds the ASCII data needed for the IP, ICMP, TCP, and UDP management information bases for an `snmp` agent. As of writing, the TCP `mib` is incomplete. It should be completed by 1.2.0.

tcp Holds a dump of the TCP socket table. Much of the information is not of use apart from debugging. The `s1` value is the kernel hash slot for the socket; the `local_address` is the local address and port number pair. The `remote_address` is the remote address and port number pair (if connected). `st` is the internal status of the socket. The `tx_queue` and `rx_queue` are the outgoing and incoming data queue in terms of kernel memory usage. The `tr`, `tm->when`, and `rexmits` fields hold internal information of the kernel socket state and are only useful for debugging. The `uid` field holds the creator euid of the socket.

udp Holds a dump of the UDP socket table. Much of the information is not of use apart from debugging. The `s1` value is the kernel hash slot for the socket; the `local_address` is the local address and port number pair. The `remote_address` is the remote address and port number pair (if connected). `st` is the internal status of the socket. The `tx_queue` and `rx_queue` are the outgoing and incoming data queue in terms of kernel memory usage. The `tr`, `tm->when`, and `rexmits` fields are not used by UDP. The `uid` field holds the creator euid of the socket. The format is

```
s1 local_address rem_address  st tx_queue rx_queue tr rexmits tm->when uid

1: 01642C89:0201 0C642C89:03FF 01 00000000:00000001 01:000071BA 00000000 0

1: 00000000:0801 00000000:0000 0A 00000000:00000000 00:00000000 6F000100 0
1: 00000000:0201 00000000:0000 0A 00000000:00000000 00:00000000 00000000 0
```

unix Lists the UNIX domain sockets present within the system and their status. The format is

```
Num RefCount Protocol Flags  Type St Path
0: 00000002 00000000 00000000 0001 03
1: 00000001 00000000 00010000 0001 01 /dev/printer
```

`Num` is the kernel table slot number, `RefCount` is the number of users of the socket, `Protocol` is currently always 0, and `Flags` represents the internal kernel flags holding the status of the socket. `Type` is currently always 1 (UNIX domain datagram sockets are not yet supported in the kernel). `St` is the internal state of the socket and `Path` is the bound path (if any) of the socket.

pci	This is a listing of all PCI devices found during kernel initialization and their configuration.
scsi	A directory with the SCSI mid-level pseudo-file and various SCSI low-level driver directories, which contain a file for each SCSI host in this system, all of which give the status of some part of the SCSI IO subsystem. These files contain ASCII structures and are therefore readable with <code>cat</code> . You can also write to some of the files to reconfigure the subsystem or switch certain features on or off.
scsi/scsi	This is a listing of all SCSI devices known to the kernel. The listing is similar to the one seen during bootup. <code>scsi</code> currently supports only the single device command, which allows root to add a hot-plugged device to the list of known devices. An echo <code>'scsisingledevice1 0 5 0'> /proc/scsi/scsi</code> will cause host <code>scsi1</code> to scan on SCSI channel 0 for a device on ID 5 LUN 0. If there is already a device known on this address or the address is invalid, an error will be returned.
drivername	<code>drivername</code> can currently be <code>NCR53c7xx</code> , <code>aha152x</code> , <code>aha1542</code> , <code>aha1740</code> , <code>aic7xxx</code> , <code>buslogic</code> , <code>eata_dma</code> , <code>eata_pio</code> , <code>fdomain</code> , <code>in2000</code> , <code>pas16</code> , <code>qllogic</code> , <code>scsi_debug</code> , <code>seagate</code> , <code>t128</code> , <code>u15-24f</code> , <code>ultrastor</code> , or <code>wd7000</code> . These directories show up for all drivers that registered at least one SCSI HBA. Every directory contains one file per registered host. Every host-file is named after the number the host got assigned during initialization. Reading these files will usually show driver and host configuration, statistics, and so on. Writing to these files allows different things on different hosts. For example, with the <code>latency</code> and <code>nolateness</code> commands, root can switch on and off command latency measurement code in the <code>eata_dma</code> driver. With the <code>lockup</code> and <code>unlock</code> commands, root can control bus lockups simulated by the <code>scsi_debug</code> driver.
self	This directory refers to the process accessing the <code>/proc</code> filesystem and is identical to the <code>/proc</code> directory named by the process ID of the same process.
stat	kernel/system statistics.
cpu 3357 0 4313 1362393	The number of jiffies (1/100ths of a second) that the system spent in user mode, user mode with low priority (<code>nice</code>), system mode, and the idle task. The last value should be 100 times the second entry in the uptime pseudo-file.
disk 0 0 0 0	The four disk entries are not implemented at this time. I'm not even sure what this should be because kernel statistics on other machines usually track both transfer rate and I/Os per second and this only allows for one field per drive.
page 5741 1808	The number of pages the system paged in and the number that were paged out (from disk).
swap 1 0	The number of swap pages that have been brought in and out.
intr 1462898	The number of interrupts received from the system boot.
ctxt 115315	The number of context switches that the system underwent.
btime 769041601	Boot time in seconds since the epoch (January 1, 1970).
sys	This directory (present since 1.3.57) contains a number of files and subdirectories corresponding to kernel variables. These variables can be read and sometimes modified using the <code>proc</code> filesystem and using the <code>sysctl(2)</code> system call. Presently, there are subdirectories <code>kernel</code> , <code>net</code> , and <code>vm</code> that each contain more files and subdirectories.
kernel	This contains the files <code>domainname</code> , <code>file-max</code> , <code>file-nr</code> , <code>hostname</code> , <code>inode-max</code> , <code>inode-nr</code> , <code>osrelease</code> , <code>ostype</code> , <code>panic</code> , <code>real-root-dev</code> , <code>securelevel</code> , and <code>version</code> , with function fairly clear from the name. The (read-only) file <code>file-nr</code> gives the number of files presently opened. The file <code>file-max</code> gives the maximum number of open files the kernel is willing to handle. If 1024 is not enough for you, try <code>echo 4096 > /proc/sys/kernel/file-max</code> . Similarly, the files <code>inode-nr</code> and <code>inode-max</code> indicate the present and the maximum number of inodes.

The files `ostype`, `osrelease`, and `version` give substrings of `/proc/version`.

The file `panic` gives r/w access to the kernel variable `panic_timeout`. If this is zero, the kernel will loop on a panic; if nonzero, it indicates that the kernel should autoreboot after this number of minutes.

The file `securelevel` seems rather meaningless at present; root is just too powerful.

`uptime`

This file contains two numbers: the uptime of the system (seconds) and the amount of time spent in idle process (seconds).

`version`

This string identifies the kernel version that is currently running. For instance:

```
Linux version 1.0.9 (quinlan@phaze) #1 Sat May 14 01:51:54 EDT 1994
```

SEE ALSO

`cat(1)`, `find(1)`, `free(1)`, `mount(1)`, `ps(1)`, `tr(1)`, `uptime(1)`, `readlink(2)`, `mmap(2)`, `chroot(2)`, `syslog(2)`, `hier(7)`, `arp(8)`, `dmesg(8)`, `netstat(8)`, `route(8)`, `ifconfig(8)`, `procinfo(8)` and much more

CONFORMS TO

This roughly conforms to a Linux 1.3.11 kernel. Please update this as necessary! Last updated for Linux 1.3.11.

CAVEATS

Note that many strings (the environment and command line) are in the internal format, with subfields terminated by null bytes, so you might find that things are more readable if you use `od -c` or `tr "\000" "\n"` to read them.

This manual page is incomplete, possibly inaccurate, and is the kind of thing that needs to be updated very often.

BUGS

The `/proc` filesystem may introduce security holes into processes running with `chroot(2)`. For example, if `/proc` is mounted in the `chroot` hierarchy, a `chdir(2)` to `/proc/1/root` will return to the original root of the filesystem. This may be considered a feature instead of a bug because Linux does not yet support the `fchroot(2)` call.

22 July 1996

protocols

`protocols`—The protocols definition file.

DESCRIPTION

This file is a plain ASCII file, describing the various DARPA Internet protocols that are available from the TCP/IP subsystem. It should be consulted instead of using the numbers in the ARPA include files or, even worse, just guessing them. These numbers will occur in the protocol field of any IP header.

Keep this file untouched because changes would result in incorrect IP packages. Protocol numbers and names are specified by the DDN Network Information Center.

Each line is of the following format:

```
protocol number aliases ...
```

The fields are delimited by spaces or tabs. Empty lines and lines starting with a hash mark (`#`) are ignored. Remainder of lines are also ignored from the occurrence of a hash mark.

The field descriptions are

`protocol`

The native name for the protocol—for example, `ip`, `tcp`, or `udp`.

`number`

The official number for this protocol as it will appear within the IP header.

`aliases`

Optional aliases for the protocol.

This file might be distributed over a network using a network-wide naming service such as Yellow Pages/NIS or BIND/Hesiod.

FILES

/etc/protocols The protocols definition file.

rcsfile

rcsfile—Format of RCS file.

DESCRIPTION

An RCS file's contents are described by the grammar below.

The text is free format: space, backspace, tab, newline, vertical tab, form feed, and carriage return (collectively, whitespace) have no significance except in strings. However, whitespace cannot appear within an ID, num, or sym, and an RCS file must end with a newline.

Strings are enclosed by @. If a string contains a @, it must be doubled; otherwise, strings can contain arbitrary binary data.

The meta syntax uses the following conventions: | (bar) separates alternatives; { and } enclose optional phrases. { and }* enclose phrases that can be repeated zero or more times. { and {+ enclose phrases that must appear at least once and can be repeated. Terminal symbols are in boldface; non-terminal symbols are in *italics*.

```
rcstext ::= adm n {del ta}* desc {del tatext}*
adm n ::= head {num};
        { branch {num}; }
        access {id}*;
        symbols {sym : num}*;
        locks {id : num}*; {strict ;}

        { comment {string}; }
        { expand {string}; }
        { newphrase }*
del ta ::= num
        date num;
        author id;
        state {id};
        branches {num}*;
        next {num};
        { new-phrase }*
desc ::= desc string
del tatext ::= num
        log string
        { newphrase }*
        text string
num ::= {digit | .}+
digit ::= 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9
id ::= {num} idchar {idchar | num}*
sym ::= {digit}* idchar {idchar | digit}*
idchar ::= any visible graphic character except special
special ::= $ | , | . | : | ; | | @
string ::= @{any character, with @doubled}*@
```

```

newphrase ::= id word* ;
word ::= id | num | string | :

```

Identifiers are case sensitive. Keywords are in lowercase only. The sets of keywords and identifiers can overlap. In most environments, RCS uses the ISO8859/1 encoding: visible graphic characters are codes 041–176 and 240–377, and whitespace characters are codes 010–015 and 040.

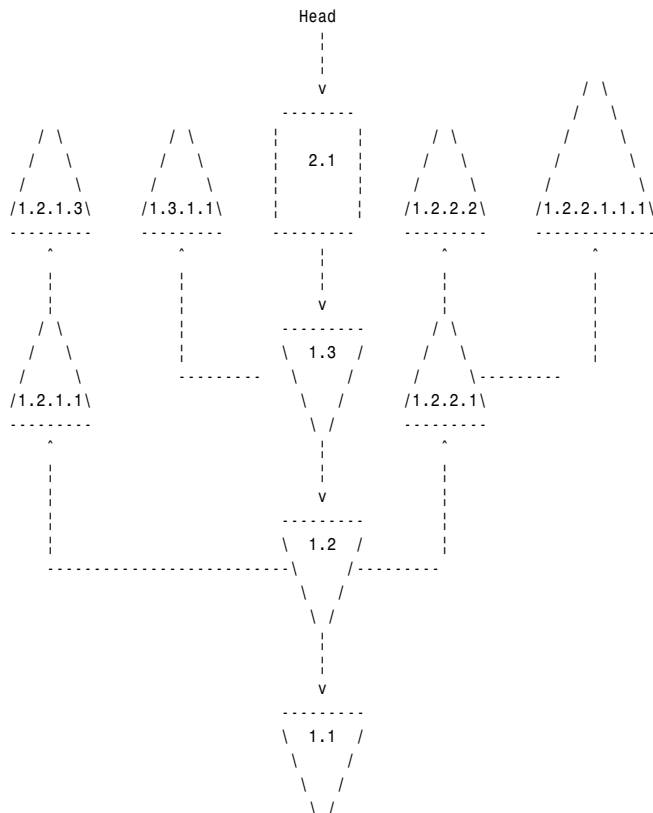

Dates, which appear after the `date` keyword, are of the form `Y.mm.dd.hh.mm.ss`, where `Y` is the year, `mm` the month (01–12), `dd` the day (01–31), `hh` the hour (00–23), `mm` the minute (00–59), and `ss` the second (00–60). `Y` contains just the last two digits of the year for years from 1900 through 1999, and all the digits of years thereafter. Dates use the Gregorian calendar; times use UTC.

The `newphrase` productions in the grammar are reserved for future extensions to the format of RCS files. No `newphrase` will begin with any keyword already in use.

The `delta` nodes form a tree. All nodes whose numbers consist of a single pair (such as 2.3, 2.1, 1.3, and so on) are on the trunk and are linked through the `next` field in order of decreasing numbers. The `head` field in the `admin` node points to the head of that sequence (contains the highest pair). The `branch` node in the `admin` node indicates the default branch (or revision) for most RCS operations. If empty, the default branch is the highest branch on the trunk.

All `delta` nodes whose numbers consist of $2n$ fields ($n \geq 2$) (such as 3.1.1.1, 2.1.2.2, and so on) are linked as follows. All nodes whose first $2n-1$ number fields are identical are linked through the `next` field in order of increasing numbers. For each such sequence, the `delta` node whose number is identical to the first $2n-2$ number fields of the deltas on that sequence is called the branchpoint. The `branches` field of a node contains a list of the numbers of the first nodes of all sequences for which it is a branchpoint. This list is ordered in increasing numbers.

The following diagram shows an example of an RCS file's organization.

GNU, 5 June 1995

resolver

resolver—Resolver configuration file.

SYNOPSIS

`/etc/resolv.conf`

DESCRIPTION

The `resolver` is a set of routines in the C library (`resolv(3)`) that provides access to the Internet Domain Name System. The resolver configuration file contains information that is read by the resolver routines the first time they are invoked by a process. The file is designed to be human readable and contains a list of keywords with values that provide various types of resolver information.

On a normally configured system, this file should not be necessary. The only nameserver to be queried will be on the local machine, the domain name is determined from the host name, and the domain search path is constructed from the domain name.

The different configuration options are

<code>nameserver</code>	Internet address (in dot notation) of a nameserver that the <code>resolver</code> should query. Up to <code>MAXNS</code> (currently 3) nameservers may be listed, one per keyword. If there are multiple servers, the resolver library queries them in the order listed. If no <code>nameserver</code> entries are present, the default is to use the nameserver on the local machine. (The algorithm used is to try a nameserver, and if the query times out, try the next until you run out of nameservers, and then repeat trying all the nameservers until a maximum number of retries are made.)
<code>domain</code>	Local domain name. Most queries for names within this domain can use short names relative to the local domain. If no domain entry is present, the domain is determined from the local hostname returned by <code>gethostname(2)</code> ; the domain part is taken to be everything after the first <code>..</code> . Finally, if the hostname does not contain a domain part, the root domain is assumed.
<code>search</code>	Search list for hostname lookup. The search list is normally determined from the local domain name; by default, it contains only the local domain name. This may be changed by listing the desired domain search path following the <code>search</code> keyword with spaces or tabs separating the names. Most <code>resolver</code> queries will be attempted using each component of the search path in turn until a match is found. Note that this process may be slow and will generate a lot of network traffic if the servers for the listed domains are not local and that queries will time out if no server is available for one of the domains. The search list is currently limited to six domains with a total of 256 characters.
<code>sortlist</code>	<code>sortlist</code> allows addresses returned by <code>gethostbyname</code> to be sorted. A sort list is specified by IP address netmask pairs. The netmask is optional and defaults to the natural netmask of the net. The IP address and optional network pairs are separated by slashes. Up to 10 pairs may be specified.

`sortlist 130.155.160.0/255.255.240.0 130.155.0.0`

`options` allows certain internal resolver variables to be modified. The syntax is `options option ...`, where `option` is one of the following:

- `debug` sets `RESDEBUG` in `res.options`.
- `ndots:n` sets a threshold for the number of dots that must appear in a name given to `res_query` (see `resolver(3)`) before an initial absolute query will be made. The default for `n` is 1, meaning that if there are any dots in a name, the name will be tried first as an absolute name before any search list elements are appended to it.

The domain and search keywords are mutually exclusive. If more than one instance of these keywords is present, the last instance wins.

The search keyword of a system's `resolv.conf` file can be overridden on a per-process basis by setting the environment variable `LOCALDOMAIN` to a space-separated list of search domains.

The `options` keyword of a system's `resolv.conf` file can be amended on a per-process basis by setting the environment variable `RES_OPTIONS` to a space-separated list of resolver options as explained previously.

The keyword and value must appear on a single line, and the keyword (such as `nameserver`) must start the line. The value follows the keyword, separated by whitespace.

securetty

`securetty`—File that lists ttys from which root can log in.

DESCRIPTION

`/etc/securetty` is used by `login(1)`; the file contains the device names of tty lines (one per line, without leading `/dev/`) on which root is allowed to log in.

FILES

`/etc/securetty`

SEE ALSO

`login(1)`

services

`services`—Internet network services list.

DESCRIPTION

`services` is a plain ASCII file providing a mapping between friendly textual names for Internet services and their underlying assigned port numbers and protocol types. Every networking program should look into this file to get the port number (and

protocol) for its service. The C library routines `getservent(3)`, `getservbyname(3)`, `getservbyport(3)`, `setservent(3)`, and `endservent(3)` support querying this file from programs.

Port numbers are assigned by the IANA (Internet Assigned Numbers Authority), and their current policy is to assign both TCP and UDP protocols when assigning a port number. Therefore, most entries will have two entries, even for TCP-only services.

Port numbers below 1024 (so-called low-numbered ports) can only be bound to by root (see `bind(2)`, `tcp(7)`, and `udp(7)`.) This is so that clients connecting to low-numbered ports can trust that the service running on the port is the standard implementation and not a rogue service run by a user of the machine. Well-known port numbers specified by the IANA are normally located in this root-only space.

The presence of an entry for a service in the `services` file does not necessarily mean that the service is currently running on the machine. See `inetd.conf(5)` for the configuration of Internet services offered. Note that not all networking services are started by `inetd(8)` and so won't appear in `inetd.conf(5)`. In particular, news (NNTP) and mail (SMTP) servers are often initialized from the system boot scripts.

The location of the `services` file is defined by `PATH SERVICES` in `/usr/include/netdb.h`. This is usually set to `/etc/services`.

Each line describes one service and is of the form:

```
service-name port/protocol [aliases ...]
```

<code>service-name</code>	The friendly name the service is known by and looked up under. It is case sensitive. Often, the client program is named after the <code>service-name</code> .
<code>port</code>	The port number (in decimal) to use for this service.
<code>protocol</code>	The type of protocol to be used. This field should match an entry in the <code>protocols(5)</code> file. Typical values include <code>tcp</code> and <code>udp</code> .
<code>aliases</code>	An optional space- or tab-separated list of other names for this service (see the Bugs section below). Again, the names are case sensitive.

Either spaces or tabs may be used to separate the fields.

Comments are started by the hash sign (#) and continue until the end of the line. Blank lines are skipped.

The `service-name` should begin in the first column of the file because leading spaces are not stripped. `service-names` can be any printable characters excluding space and tab; however, a conservative choice of characters should be used to minimize inter-operability problems. For example, a-z, 0-9, and hyphen (-) would seem a sensible choice.

Lines not matching this format should not be present in the file. (Currently, they are silently skipped by `getservent(3)`, `getservbyname(3)`, and `getservbyport(3)`. However, this behavior should not be relied on.)

As a backwards compatibility feature, the slash (/) between the port number and protocol name can in fact be either a slash or a comma (,). Use of the comma in modern installations is deprecated.

This file might be distributed over a network using a network-wide naming service such as Yellow Pages/NIS or BIND/Hesiod.

A sample `services` file might look like this:

```
netstat    15/tcp
qotd      17/tcp    quote
msp       18/tcp    # message send protocol
msp       18/udp    # message send protocol
chargen   19/tcp    ttytst source
chargen   19/udp    ttytst source
ftp       21/tcp
#         22 - unassigned
telnet    23/tcp
```

BUGS

There is a maximum of 35 aliases, due to the way the `getservernt(3)` code is written.

Lines longer than `BUFSIZ` (currently 1024) characters will be ignored by `getservernt(3)`, `getservbyname(3)`, and `getservbyport(3)`. However, this will also cause the next line to be misparsed.

shells

`shells`—Pathnames of valid login shells.

DESCRIPTION

`/etc/shells` is a text file that contains the full pathnames of valid login shells. This file is consulted by `chsh(1)` and is available to be queried by other programs.

EXAMPLES

`/etc/shells` may contain the following paths:

```
/bin/sh
/bin/csh
```

FILES

`/etc/shells`

syslog.conf

`syslog.conf`—`syslogd(8)` configuration file.

DESCRIPTION

The `syslog.conf` file is the configuration file for the `syslogd(8)` program. It consists of lines with two fields: the `selector` field, which specifies the types of messages and priorities to which the line applies, and an `action` field, which specifies the action to be taken if a message `syslogd` received matches the selection criteria. There cannot be any spaces in the `action` field. The `selector` field is separated from the `action` field by one or more tab or space characters. (This is a departure from the standard BSD way of doing things; both tabs and spaces can be used to separate the selector from the action.)

The `selector` functions are encoded as a facility, a period (`.`), and a level, with no intervening whitespace. Both the facility and the level are case insensitive.

```
# Root and Eric get alert and higher messages.
*.alert                                root,eric

# Save mail and news errors of level err and higher in a
# special file.
uucp,news.crit                          /var/log/spoolerr
```

FILES

`/etc/syslog.conf` The `syslogd(8)` configuration file.

BUGS

The effects of multiple selectors are sometimes not intuitive. For example `mail.crit,*.err` will select mail facility messages at the level of `err` or higher, not at the level of `crit` or higher.

termcap

`termcap`—Terminal capability database.

DESCRIPTION

The `termcap` database is an obsolete facility for describing the capabilities of character-cell terminals and printers. It is retained only for capability with old programs; new ones should use the `terminfo(5)` database and associated libraries.

`/etc/termcap` is an ASCII file (the database master) that lists the capabilities of many different types of terminals. Programs can read `termcap` to find the particular escape codes needed to control the visual attributes of the terminal actually in use. (Other aspects of the terminal are handled by `stty`.) The `termcap` database is indexed on the `TERM` environment variable.

`termcap` entries must be defined on a single logical line, with `\` used to suppress the newline. Fields are separated by `:`. The first field of each entry starts at the left-hand margin and contains a list of names for the terminal, separated by `|`.

The first subfield may (in BSD `termcap` entries from versions 4.3 and prior) contain a short name consisting of two characters. This short name may consist of capital or small letters. In 4.4 BSD `termcap` entries, this field is omitted.

The second subfield (first in the newer 4.4 BSD format) contains the name used by the environment variable `TERM`. It should be spelled in lowercase letters. Selectable hardware capabilities should be marked by appending a hyphen and a suffix to this name. Usual suffixes are `w` (more than 80 characters wide), `am` (automatic margins), `nam` (no automatic margins) and `rv` (reverse video display). The third subfield contains a long and descriptive name for this `termcap` entry.

Subsequent fields contain the terminal capabilities; any continued capability lines must be indented one tab from the left margin.

Although there is no defined order, it is suggested to write first Boolean, then numeric, and at last string capabilities, each sorted alphabetically without looking at lower or upper spelling. Capabilities of similar functions can be written in one line.

Example:

```
Head line: vt|vt101|DEC VT 101 terminal in 80 character mode:\
Head line: Vt|vt101-w|DEC VT 101 terminal in (wide) 132 character mode:\
Boolean: :bs:\
Numeric: :co#80:\
String: :sr=nE[H:\
```

Boolean Capabilities

5i	Printer will not echo on screen
am	Automatic margins which means automatic line wrap
bs	Ctrl+H (8 dec.) performs a backspace
bw	Backspace on left margin wraps to previous line and right margin
da	Display retained above screen
db	Display retained below screen
eo	A space erases all characters at cursor position
es	Escape sequences and special characters work in status line
gn	Generic device
hc	This is a hardcopy terminal
HC	The cursor is hard to see when not on bottom line
hs	Has a status line
hz	Hazeltine bug; the terminal cannot print tilde characters
in	Terminal inserts nulls, not spaces, to fill whitespace
km	Terminal has a meta key
mi	Cursor movement works in insert mode
ms	Cursor movement works in standout/underline mode
NP	No pad character
NR	ti does not reverse te
nx	No padding; must use XON/XOFF
os	Terminal can overstrike
ul	Terminal underlines, although it cannot overstrike
xb	Beehive glitch; F1 sends Escape and F2 sends ^C
xn	Newline/wraparound glitch
xo	Terminal uses XON/XOFF protocol
xs	Text typed over standout text will be displayed in standout
xt	Teleray glitch; destructive tabs and odd standout mode

Numeric Capabilities

co	Number of columns
dB	Delay in milliseconds for backspace on hardcopy terminals
dC	Delay in milliseconds for carriage return on hardcopy terminals
dF	Delay in milliseconds for form feed on hardcopy terminals
dN	Delay in milliseconds for newline on hardcopy terminals
dT	Delay in milliseconds for tabulator stop on hardcopy terminals
dV	Delay in milliseconds for vertical tabulator stop on hardcopy terminals
it	Difference between tab positions
lh	Height of soft labels
lm	Lines of memory
lw	Width of soft labels

continues

Numeric Capabilities

li	Number of lines
Nl	Number of soft labels
pb	Lowest baud rate that needs padding
sg	Standout glitch
ug	Underline glitch
vt	Virtual terminal number
ws	Width of status line if different from screen width

String Capabilities

!1	Shifted save key
!2	Shifted suspend key
!3	Shifted undo key
#1	Shifted help key
#2	Shifted home key
#3	Shifted input key
#4	Shifted cursor left key

%g	Shifted redo key
%h	Shifted replace key
%i	Shifted cursor right key
%j	Shifted resume key
&0	Shifted cancel key
&1	Reference key
&2	Refresh key
&3	Replace key
&4	Restart key

String Capabilities

&5	Resume key
&6	Save key
&7	Suspend key
&8	Undo key
&9	Shifted begin key
*0	Shifted find key
*1	Shifted command key
*2	Shifted copy key
*3	Shifted create key
*4	Shifted delete character
*5	Shifted delete line
*6	Select key
*7	Shifted end key
*8	Shifted clear line key
*9	Shifted exit key
@0	Find key
@1	Begin key
@2	Cancel key
@3	Close key
@4	Command key
@5	Copy key
@6	Create key
@7	End key
@8	Enter/send key
@9	Exit key
a1	Insert one line
AL	Insert %1 lines
ac	Pairs of block graphic characters to map alternate character set
ae	End alternative character set
as	Start alternative character set for block graphic characters
bc	Backspace if not <code>^H</code>
b1	Audio bell
bt	Move to previous tab stop
cb	Clear from beginning of line to cursor
cc	Dummy command character
cd	Clear to end of screen
ce	Clear to end of line
ch	Move cursor horizontally only to column %1
c1	Clear screen and cursor home
cm	Cursor move to row %1 and column %2 (on screen)
CM	Move cursor to row %1 and column %2 (in memory)

continues

String Capabilities

cr	Carriage return
cs	Scroll region from line %1 to %2
ct	Clear tabs
cv	Move cursor vertically only to line %1
dc	Delete one character
DC	Delete %1 characters
d1	Delete one line
DL	Delete %1 lines
dm	Begin delete mode
do	Cursor down one line
DO	Cursor down #1 lines
ds	Disable status line
eA	Enable alternate character set
ec	Erase %1 characters starting at cursor
ed	End delete mode
ei	End insert mode
ff	Formfeed character on hardcopy terminals
fs	Return character to its position before going to status line
F1	The string sent by function key f11

k;	Function key 10
ka	Clear all tabs key
kA	Insert line key
kb	Backspace key
kB	Back tab stop
kC	Clear screen key
kd	Cursor down key
kD	Key for delete character under cursor
ke	Turn keypad off
kE	Key for clear to end of line
kF	Key for scrolling forward/down
kh	Cursor home key
kH	Cursor down key
kI	Insert character/insert mode key
kL	Cursor left key
kL	Key for delete line
kM	Key for exit insert mode
kN	Key for next page
kP	Key for previous page
kr	Cursor right key
kR	Key for scrolling backward/up
ks	Turn keypad on
kS	Clear to end of screen key
kt	Clear this tab key

continues

String Capabilities

kT	Set tab here key
ku	Cursor up key
l0	Label of zeroth function key, if not f0
l1	Label of first function key, if not f1
l2	Label of first function key, if not f2
...	...
l _a	Label of tenth function key, if not f10
le	Cursor left one character
ll	Move cursor to lower-left corner
LE	Cursor left %1 characters
LF	Turn soft labels off
LO	Turn soft labels on
mb	Start blinking
MC	Clear soft margins
md	Start bold mode
me	End all modes such as so, us, mb, md, and mr
mh	Start half bright mode
mk	Dark mode (Characters invisible)
ML	Set left soft margin
mm	Put terminal in meta mode
mo	Put terminal out of meta mode
mp	Turn on protected attribute
mr	Start reverse mode
MR	Set right soft margin
nd	Cursor right one character
nw	Carriage return command
pc	Padding character
pf	Turn printer off
pk	Program key %1 to send string %2 as if typed by user
pl	Program key %1 to execute string %2 in local mode
pn	Program soft label %1 to show string %2
po	Turn the printer on
p0	Turn the printer on for %1 (<256) bytes
ps	Print screen contents on printer
px	Program key %1 to send string %2 to computer
r1	Reset string 1 to set terminal to sane modes
r2	Reset string 2 to set terminal to sane modes
r3	Reset string 3 to set terminal to sane modes
RA	Disable automatic margins
rc	Restore saved cursor position
rf	Reset string file name

String Capabilities

RF	Request for input from terminal
RI	Cursor right %1 characters
rp	Repeat character %1 for %2 times
rP	Padding after character sent in replace mode
rs	Reset string
RX	Turn off XON/XOFF flow control
sa	Set %1 %2 %3 %4 %5 %6%7 %8 %9 attributes
SA	Enable automatic margins
sc	Save cursor position
se	End standout mode
sf	Normal scroll one line
SF	Normal scroll %1 lines
so	Start standout mode
sr	Reverse scroll
SR	Scroll back %1 lines
st	Set tabulator stop in all rows at current column
SX	Turn on XON/XOFF flow control
ta	Move to next hardware tab
tc	Read in terminal description from another entry
te	End program that uses cursor motion
ti	Begin program that uses cursor motion
ts	Move cursor to column %1 of status line
uc	Underline character under cursor and move cursor right
ue	End underlining
up	Cursor up one line
UP	Cursor up %1 lines
us	Start underlining
vb	Visible bell
ve	Normal cursor visible
vi	Cursor invisible
vs	Standout cursor
wi	Set window from line %1 to %2 and column %3 to %4
XF	XOFF character if not ^S

There are several ways of defining the control codes for string capabilities:

Normal characters except ^, \, and % represent themselves.

A ^x means Ctrl+x. Ctrl+A equals 1 decimal. \x means a special code. x can be one of the following characters:

E	Escape (27).
n	Linefeed (10).
r	Carriage return (13).
t	Tabulation (9).

b	Backspace (8).
f	Form feed (12).
0	Null character. A \xxx specifies the octal character xxx.
i	Increments parameters by one.
r	Single parameter capability.
+	Add value of next character to this parameter and do binary output.
2	Do ASCII output of this parameter with a field width of 2.
d	Do ASCII output of this parameter with a field width of 3.
%	Print a %

If you use binary output, then you should avoid the null character because it terminates the string. You should reset tabulator expansion if a tabulator can be the binary output of a parameter.

Warning: The preceding metacharacters for parameters may be wrong; they document Minix `termcap`, which may not be compatible with Linux `termcap`.

The block graphic characters can be specified by three string capabilities:

as	Start the alternative charset.
ae	End it.
ac	Pairs of characters. The first character is the name of the block graphic symbol and the second character is its definition.

The following names are available:

+	Right arrow (>)
,	Left arrow (<)
.	Down arrow (v)
0	Full square (#)
I	Latern (#)
-	Upper arrow (^)
,	Rhombus (+)
a	Chess board (:)
f	Degree (°)
g	Plus-minus (#)
h	Square (#)
j	Right bottom corner (+)
k	Right upper corner (+)
l	Left upper corner (+)
m	Left bottom corner (+)
n	Cross (+)
o	Upper horizontal line (-)
q	Middle horizontal line (-)
s	Bottom horizontal line (⏟)
t	Left tee (+)
u	Right tee (+)
v	Bottom tee (+)
w	Normal tee (+)
x	Vertical line (⏟)
-	Paragraph (???)

The values in parentheses are suggested defaults that are used by `curses` if the capabilities are missing.

Linux

ttytype

`ttytype`—Terminal name and device list.

DESCRIPTION

The `/etc/ttytype` file associates `termcap/terminfo` terminal type names with `tty` lines. Each line consists of a terminal type, followed by whitespace, followed by a `tty` name (a device name without the `/dev/` prefix).

This association is used by the program `tset(1)` to set the environment variable `TERM` to the default terminal name for the user's current `tty`.

This facility was designed for a traditional time-sharing environment featuring character-cell terminals hardwired to a UNIX minicomputer. It is little used on modern workstation and personal UNIXes.

EXAMPLE

A typical `/etc/ttytype` is

```
con80x25 tty1
vt320 ttys0
```

FILES

`/etc/ttytype` The `tty` definitions file

Linux, 24 July 1993

tzfile

`tzfile`—Time zone information.

SYNOPSIS

```
#include <tzfile.h>
```

DESCRIPTION

The time zone information files used by `tzset(3)` begin with bytes reserved for future use, followed by six four-byte values of type `long`, written in a “standard” byte order (the high-order byte of the value is written first). These values are, in order

<code>tz_ttisgmtcnt</code>	The number of GMT/local indicators stored in the file.
<code>tz_ttisstdcnt</code>	The number of standard/wall indicators stored in the file.
<code>tz_leapcnt</code>	The number of leap seconds for which data is stored in the file.
<code>tz_timecnt</code>	The number of “transition times” for which data is stored in the file.
<code>tz_typecnt</code>	The number of “local time types” for which data is stored in the file (must not be zero).
<code>tz_charcnt</code>	The number of characters of “time zone abbreviation strings” stored in the file.

The preceding header is followed by `tzh_timecnt` four-byte values of type `long`, sorted in ascending order. These values are written in “standard” byte order. Each is used as a transition time (as returned by `time(2)`) at which the rules for computing local time change. Next come `tzh_timecnt` one-byte values of type `unsigned char`; each one tells which of the different types of “local time” types described in the file is associated with the same-indexed transition time. These values serve as indices into an array of `ttinfo` structures that appears next in the file; these structures are defined as follows:

```
struct ttinfo {
    long tt_gmtoff;
    int tt_isdst;
    unsigned int tt_abbrind;
};
```

Each structure is written as a four-byte value for `tt_gmtoff` of type `long`, in a standard byte order, followed by a one-byte value for `tt_isdst` and a one-byte value for `tt_abbrind`. In each structure, `tt_gmtoff` gives the number of seconds to be added to GMT, `tt_isdst` tells whether `tm_isdst` should be set by `localtime(3)` and `tt_abbrind` serves as an index into the array of time zone abbreviation characters that follow the `ttinfo` structures in the file.

Then there are `tzh_leapcnt` pairs of four-byte values, written in standard byte order; the first value of each pair gives the time (as returned by `time(2)`) at which a leap second occurs; the second gives the total number of leap seconds to be applied after the given time. The pairs of values are sorted in ascending order by time.

Then there are `tzh_ttisstdcnt` standard/wall indicators, each stored as a one-byte value; they tell whether the transition times associated with local time types were specified as standard time or wall clock time and are used when a time zone file is used in handling POSIX-style time zone environment variables.

Finally, there are `tzh_ttisgmtcnt` GMT/local indicators, each stored as a one-byte value; they tell whether the transition times associated with local time types were specified as GMT or local time and are used when a time zone file is used in handling POSIX-style time zone environment variables.

`Localtime` uses the first standard-time `ttinfo` structure in the file (or simply the first `ttinfo` structure in the absence of a standard-time structure) if either `tzh_timecnt` is zero or the time argument is less than the first transition time recorded in the file.

SEE ALSO

`newctime(3)`

utmp, wtmp

`utmp`, `wtmp`—Login records.

SYNOPSIS

```
#include <utmp.h>
```

DESCRIPTION

The `utmp` file allows you to discover information about who is currently using the system. There may be more users currently using the system because not all programs use `utmp` logging.

Warning: `utmp` must not be writable because many system programs depend on its integrity. You risk faked system log files and modifications of system files if you leave `utmp` writable to any user.

The file is a sequence of entries with the following structure declared in the include file:

```
#define UT_UNKNOWN 0
#define RUN_LVL 1
#define BOOT_TIME 2
#define NEW_TIME 3
#define OLD_TIME 4
```

```

#define INIT_PROCESS 5
#define LOGIN_PROCESS 6
#define USER_PROCESS 7
#define DEAD_PROCESS 8

#define UT_LINESIZE 12
#define UT_NAMESIZE 8
#define UT_HOSTSIZE 16

struct utmp {
    short ut_type;           /* type of login */
    pid_t ut_pid;           /* pid of process */
    char ut_line[UT_LINESIZE]; /* device name of tty - "/dev/" */
    char ut_id[2];          /* init id or abbrev. ttyname */
    time_t ut_time;         /* login time */
    char ut_user[UT_NAMESIZE]; /* user name */
    char ut_host[UT_HOSTSIZE]; /* host name for remote login */
    long ut_addr;           /* IP addr of remote host */
};

```

This structure gives the name of the special file associated with the user's terminal, the user's login name, and the time of login in the form of `time(2)`. String fields are terminated by `\0` if they are shorter than the size of the field.

The first entries ever created result from `init(8)` processing `inittab(5)`. Before an entry is processed, though, `init(8)` cleans up `utmp` by setting `ut_type` to `DEAD_PROCESS`, clearing `ut_user`, `ut_host` and `ut_time` with null bytes for each record that `ut_type` is not `DEAD_PROCESS` or `RUN_LVL` and where no process with PID `ut_pid` exists. If no empty record with the needed `ut_id` can be found, `init` creates a new one. It sets `ut_id` from the `inittab`, `ut_pid` and `ut_time` to the current values, and `ut_type` to `INIT_PROCESS`.

`getty(8)` locates the entry by the PID, changes `ut_type` to `LOGIN_PROCESS`, changes `ut_time`, sets `ut_line` and waits for connection to be established. `login(8)`, after a user has been authenticated, changes `ut_type` to `USER_PROCESS`, changes `ut_time`, and sets `ut_host` and `ut_addr`. Depending on `getty(8)` and `login(8)`, records may be located by `ut_line` instead of the preferable `ut_pid`.

When `init(8)` finds that a process has exited, it locates its `utmp` entry by `ut_pid`, sets `ut_type` to `DEAD_PROCESS`, and clears `ut_user`, `ut_host`, and `ut_time` with null bytes.

`xterm(1)` and other terminal emulators directly create a `USER_PROCESS` record and generate the `ut_id` by using the last two letters of `/dev/tty%c` or by using `p%d` for `/dev/pts/%d`.

If they find a `DEAD_PROCESS` for this ID, they recycle it; otherwise, they create a new entry. If they can, they will mark it as `DEAD_PROCESS` on exiting and it is advised that they null `ut_line`, `ut_time`, `ut_user`, and `ut_host` as well.

`xdm(8)` should not create an `utmp` record because there is no assigned terminal. Letting it create one will result in trouble such as `finger: cannot stat /dev/machine.dom`. It should create `wtmp` entries, though, just like `ftpd(8)` does.

`telnetd(8)` sets up a `LOGIN_PROCESS` entry and leaves the rest to `login(8)` as usual. After the Telnet session ends, `telnetd(8)` cleans up `utmp` in the described way.

The `wtmp` file records all logins and logouts. Its format is exactly like `utmp` except that a null username indicates a logout on the associated terminal. Furthermore, the terminal name `~` with username `shutdown` or `reboot` indicates a system shutdown or reboot and the pair of terminal names `"|"/"` logs the old/new system time when `date(1)` changes it. `wtmp` is maintained by `login(1)` and `init(1)` and some variation of `getty(1)`. Neither of these programs creates the file, so if it is removed, record-keeping is turned off.

FILES

```

/var/run/utmp
/var/log/wtmp

```

CONFORMING TO

Linux `utmp` entries conform neither to v7/BSD nor to SYSV: They are a mix of the two. v7/BSD has fewer fields; most importantly, it lacks `ut_type`, which causes native v7/BSD-like programs to display (for example) dead or login entries. Further there is no configuration file that allocates slots to sessions. BSD does so because it lacks `ut_id` fields. In Linux (as in SYSV), the `ut_id` field of a record will never change once it is set, which reserves that slot without needing a configuration file. Clearing `ut_id` may result in race conditions leading to corrupted `utmp` entries and potential security holes. Clearing the previously mentioned fields by filling them with null bytes is not required by SYSV semantics, but it allows you to run many programs that assume BSD semantics and that do not modify `utmp`. Linux uses the BSD conventions for line contents. SYSV only uses the type field to mark them and logs informative messages such as `new time` in the line field. SYSV has one more field to log the exit status of dead processes. `UT_UNKNOWN` seems to be a Linux invention. There is no type `ACCOUNTING` in Linux. SYSV has no `ut_host` or `ut_addr` fields. Unlike various other systems, where `utmp` logging can be disabled by removing the file, `utmp` must always exist on Linux. If you want to disable `who(1)`, then do not make `utmp` world readable.

RESTRICTIONS

The file format is machine dependent, so it is recommended that it be processed only on the machine architecture where it got created.

uuencode

`uuencode`—Format of an encoded uuencode file.

DESCRIPTION

Files output by `uuencode(1)` consist of a header line, followed by a number of body lines, and a trailer line. The `uudecode(1)` command will ignore any lines preceding the header or following the trailer. Lines preceding a header must not, of course, look like a header.

The header line is distinguished by having the first six characters `begin`. The word `begin` is followed by a mode (in octal) and a string that names the remote file. A space separates the three items in the header line.

The body consists of a number of lines, each at most 62 characters long (including the trailing newline). These consist of a character count, followed by encoded characters, followed by a newline. The character count is a single printing character and represents an integer, the number of bytes the rest of the line represents. Such integers are always in the range from 0 to 63 and can be determined by subtracting the character space (octal 40) from the character.

Groups of three bytes are stored in four characters, six bits per character. All are offset by a space to make the characters print. The last line may be shorter than the normal 45 bytes. If the size is not a multiple of three, this fact can be determined by the value of the count on the last line. Extra garbage will be included to make the character count a multiple of four. The body is terminated by a line with a count of zero. This line consists of one ASCII space.

The trailer line consists of `end` on a line by itself.

`uuencode(1)`, `uudecode(1)`, `uuseed(1)`, `uucp(1)`, `mail(1)`

HISTORY

The uuencode file format appeared in BSD 4.0.

XF86Config

XF86Config—Configuration file for XFree86.

DESCRIPTION

XFree86 uses a configuration file called `XF86Config` for its initial setup. This configuration file is searched for in the following places:

```
/etc/XF86Config
<XRoot>/lib/X11/XF86Config.hostname
<XRoot>/lib/X11/XF86Config
```

<XRoot> refers to the root of the X11 install tree.

This file is composed of a number of sections. Each section has the form:

```
Section "SectionName"
SectionEntry ...
EndSection
```

The section names are

Files	File pathnames
ServerFlags	Server flags
Keyboard	Keyboard configuration
Pointer	Pointer configuration
Monitor	Monitor description
Device	Graphics device description
Screen	Screen configuration

The `Files` section is used to specify the default font path and the path to the RGB database. These paths can also be set from the command line (see `Xserver(1)`). The entries available for this section are

FontPath "path"	Sets the search path for fonts. This path is a comma-separated list of directories that the X server searches for font databases. Multiple <code>FontPath</code> entries may be specified, and they will be concatenated to build up the fontpath used by the server. X11R6 allows the X server to request fonts from a font server. A font server is specified by placing a "<trans>/<hostname>:<port_number>" entry into the fontpath. For example, the fontpath "/usr/X11R6/lib/X11/fonts/misc/,tcp/zok:7100" tells the X server to first try to locate the font in the local directory <code>/usr/X11R6/lib/X11/fonts/misc</code> . If that fails, then request the font from the font server running on machine <code>zok</code> listening for connections on TCP port number <code>7100</code> .
RGBPath "path"	Sets the path name for the RGB color database.

The `ServerFlags` section is used to specify some miscellaneous X server options. The entries available for this section are

NoTrapSignals	This prevents the X server from trapping a range of unexpected fatal signals and exiting cleanly. Instead, the X server will die and drop core where the fault occurred. The default behavior is for the X server exit cleanly but still drop a core file. In general, you never want to use this option unless you are debugging an X server problem.
DontZap	This disallows the use of the <code>Ctrl+Alt+Backspace</code> sequence. This sequence allows you to terminate the X server. Setting <code>DontZap</code> allows this key sequence to be passed to clients.
DontZoom	This disallows the use of the <code>Ctrl+Alt+Keypad-Plus</code> and <code>Ctrl+Alt+Keypad-Minus</code> sequences. These sequences allow you to switch between video modes. Setting <code>DontZoom</code> allows these key sequences to be passed to clients.

The `Keyboard` section is used to specify the keyboard input device, parameters, and some default keyboard mapping options. The entries available for this section are

`Protocol "kbd-protocol "` `kbd-protocol` may be either `Standard` or `Xqueue`. `Xqueue` is specified when using the event queue driver on `SVR3` or `SVR4`.

`AutoRepeat delay rate` Changes the behavior of the autorepeat of the keyboard. This does not work on all platforms.

`ServerNumLock` Forces the X server to handle the numlock key internally. The X server sends a different set of keycodes for the numpad when the numlock key is active. This enables applications to make use of the numpad.

`LeftAlt mapping` `RightAlt mapping` `AltGr mapping`
`ScrollLock mapping` `RightCtl mapping`

Allows a default mapping to be set for the preceding keys (note that `AltGr` is a synonym for `RightAlt`). The values that may be specified for mapping are

`Meta`
`Compose`
`ModeShift`
`ModeLock`
`ScrollLock`
`Control`

The default mapping when none of these options are specified is

`LeftAlt Meta`

`RightAlt Meta`

`ScrollLock Compose`

`RightCtl Control`

`XLeds led ...` Makes `led` available for clients instead of using the traditional function (`Scroll Lock`, `Caps Lock`, and `Num Lock`). `led` is a list of numbers in the range 1 to 3.

`VTSysReq` Enables the `SYSV`-style VT switch sequence for non-`SYSV` systems that support VT switching. This sequence is `Alt-SysRq` followed by a function key (`F n`). This prevents the X server trapping the keys used for the default VT switch sequence.

`VTInit "command"` Runs `command` after the VT used by the server has been opened. The command string is passed to `/bin/sh -c` and is run with the real user's ID with `stdin` and `stdout` set to the VT. The purpose of this option is to allow system-dependent VT initialization commands to be run. One example is a command to disable the two-key VT switching sequence that is the default on some systems.

The `Pointer` section is used to specify the pointer device and parameters. The entries available for this section are

`Protocol "protocol -type"` Specifies the pointer device protocol type. The protocol types available are

`BusMouse`
`Logitech`
`Microsoft`
`MMSeries`
`Mouseman`
`MouseSystems`
`PS/2`

MMHitTab
 Xqueue
 OSMouse

One should specify `BusMouse` for the Logitech bus mouse. Also, many newer Logitech serial mice use either the `Microsoft` or `MouseMan` protocol. `Xqueue` should be specified here if it was used in the `Keyboard` section. `OSMouse` refers to the event-driver mouse interface available on SCO's SVR3. This may optionally be followed by a number specifying the number of buttons the mouse has.

Device "pointer-dev"	Specifies the device the server should open for pointer input (such as <code>/dev/tty00</code> or <code>/dev/mouse</code>). A device should not be specified when using the <code>Xqueue</code> or <code>OSMouse</code> protocols.
BaudRate rate	Sets the baud rate of the serial mouse to <code>rate</code> . For mice that allow dynamic speed adjustments (such as Logitech), the baud rate is changed in the mouse. Otherwise, the rate is simply set on the computer's side to allow mice with non-standard rates (the standard rate is 1200).
Emulate3Buttons	Enables the emulation of the third mouse button for mice that only have two physical buttons. The third button is emulated by pressing both buttons simultaneously.
Emulate3Timeout timeout	Sets the time (in milliseconds) that the server waits before deciding if two buttons were pressed "simultaneously" when three-button emulation is enabled. The default time-out is 50ms.
ChordMiddle	Handles mice that send left+right events when the middle button is used (such as some Logitech Mouseman mice).
SampleRate rate	Sets the number of motion/button-events the mouse sends per second. This is currently only supported for some Logitech mice.
ClearDTR	This option clears the DTR line on the serial port used by the mouse. This option is only valid for a mouse using the <code>MouseSystems</code> protocol. Some dual-protocol mice require DTR to be cleared to operate in <code>MouseSystems</code> mode. Note, in versions of XFree86 prior to 2.1, this option also cleared the RTS line. A separate <code>ClearRTS</code> option has since been added for mice that require this.
ClearRTS	This option clears the RTS line on the serial port used by the mouse. This option is only valid for a mouse using the <code>MouseSystems</code> protocol. Some dual-protocol mice require both DTR and RTS to be cleared to operate in <code>MouseSystems</code> mode. Both the <code>ClearDTR</code> and <code>ClearRTS</code> options should be used for such mice.

The `Monitor` sections are used to define the specifications of a monitor and a list of video modes suitable for use with a monitor. More than one `Monitor` section may be present in an `XF86Config` file. The entries available for this section are

Identifier "ID string"	This specifies a string by which the monitor can be referred to in a later <code>Screen</code> section. Each <code>Monitor</code> section should have a unique ID string.
VendorName "vendor"	This optional entry specifies the monitor's manufacturer.
ModelName "model"	This optional entry specifies the monitor's model.
HorizSync hori zsync-range	Gives the ranges of horizontal sync frequencies supported by the monitor. <code>hori zsync-range</code> may be a comma-separated list of either discrete values or ranges of values. A range of values is two values separated by a dash. By default, the values are in units of kHz. They may be specified in MHz or Hz if MHz or Hz is added to the end of the line. The data given here is used by the X server to determine if video modes are within the specifications of the monitor. This information should be available in the monitor's handbook.

VertRefresh vertrefresh-range

Gives the ranges of vertical refresh frequencies supported by the monitor. `vertrefresh-range` may be a comma-separated list of either discrete values or ranges of values. A range of values is two values separated by a dash. By default, the values are in units of Hz. They may be specified in MHz or kHz if MHz or kHz is added to the end of the line. The data given here is used by the X server to determine if video modes are within the specifications of the monitor. This information should be available in the monitor's handbook.

Gamma gamma-values

This is an optional entry that can be used to specify the gamma correction for the monitor. It may be specified as either a single value or as three separate RGB values. Not all X servers are capable of using this information.

Mode "name"

Indicates the start of a multi-line video mode description. The mode description is terminated with an End-Mode line. The mode description consists of the following entries:

DotClock clock

The dot clock rate to be used for the mode.

HTimings hdisp hsyncstart hsyncend htotal

Specifies the horizontal timings for the mode.

VTimings vdisp vsyncstart vsyncend vtotal

Specifies the vertical timings for the mode.

Flags "flag" ...

Specifies an optional set of mode flags. `Interlace` indicates that the mode is interlaced. `DoubleScan` indicates a mode where each scanline is doubled. `+HSync` and `-HSync` can be used to select the polarity of the HSync signal. `+VSync` and `-VSync` can be used to select the polarity of the VSync signal. `Composite` can be used to specify composite sync on hardware where this is supported. Additionally, on some hardware, `+CSync` and `-CSync` may be used to select the composite sync polarity.

Modeline "name" mode-description

A single line format for specifying video modes. The `mode-description` is in four sections, the first three of which are mandatory. The first is the pixel clock. This is a single number specifying the pixel clock rate for the mode. The second section is a list of four numbers specifying the horizontal timings. These numbers are the `hdisp`, `hsyncstart`, `hsyncend`, `htotal`. The third section is a list of four numbers specifying the vertical timings. These numbers are `vdisp`, `vsyncstart`, `vsyncend`, `vtotal`. The final section is a list of flags specifying other characteristics of the mode. `Interlace` indicates that the mode is interlaced. `DoubleScan` indicates a mode where each scanline is doubled. `+HSync` and `-HSync` can be used to select the polarity of the HSync signal. `+VSync` and `-VSync` can be used to select the polarity of the VSync signal. `Composite` can be used to specify composite sync on hardware where this is supported. Additionally, on some hardware, `+CSync` and `-CSync` may be used to select the composite sync polarity.

The `Device` sections are used to define a graphics device (video board). More than one `Device` section may be present in an `XF86Config` file. The entries available for this section are

Identifier "ID string"

This specifies a string by which the graphics device can be referred to in a later `Screen` section. Each `Device` section should have a unique ID string.

VendorName "vendor"

This optional entry specifies the graphics device's manufacturer.

BoardName "model"

This optional entry specifies the name of the graphics device.

Chipset "chipset-type"

This optional entry specifies the chipset used on the graphics board. In most cases, this entry is not required because the X servers will probe the hardware to determine the chipset type.

Ramdac "ramdac-type"	This optional entry specifies the type of RAMDAC used on the graphics board. This is only used by a few of the X servers, and in most cases, it is not required because the X servers will probe the hardware to determine the RAMDAC type where possible.
DacSpeed speed	This optional entry specifies the RAMDAC speed rating (which is usually printed on the RAMDAC chip). The speed is in MHz. This is only used by a few of the X servers and only needs to be specified when the speed rating of the RAMDAC is different from the default built in to the X server.
Clocks clock ...	Specifies the dotclocks that are on your graphics board. The clocks are in MHz and may be specified as a floating-point number. The value is stored internally to the nearest kHz. The ordering of the clocks is important. It must match the order in which they are selected on the graphics board. Multiple <code>Clocks</code> lines may be specified. For boards with programmable clock chips, the <code>ClockChip</code> entry should be used instead of this. A <code>Clocks</code> entry is not mandatory for boards with non-programmable clock chips but is highly recommended because it prevents the clock probing phase during server startup. This clock probing phase can cause problems for some monitors.
ClockChip "clockchip-type"	This optional entry is used to specify the clock chip type on graphics boards that have a programmable clock generator. Only a few X servers support programmable clock chips. For details, see the appropriate X server manual page.
ClockProg command [textclock]	This optional entry runs <code>command</code> to set the clock on the graphics board instead of using the internal code. The command string must consist of the full pathname (and no flags). When using this option, a <code>Clocks</code> entry is required to specify which clock values are to be made available to the server (up to 128 clocks may be specified). The optional <code>textclock</code> value is to tell the server that <code>command</code> must be run to restore the text-mode clock at server exit (or when VT switching). <code>textclock</code> must match one of the values in the <code>Clocks</code> entry. This parameter is required when the clock used for text mode is a programmable clock. The command is run with the real user's ID with <code>stdin</code> and <code>stdout</code> set to the graphics console device. Two arguments are passed to the command. The first is the clock frequency in MHz as a floating-point number and the second is the index of the clock in the <code>Clocks</code> entry. The command should return an exit status of 0 when successful and something in the range 1–254 otherwise. The <code>command</code> is run when the initial graphics mode is set and when changing screen resolution with the hotkey sequences. If the program fails at initialization, the server exits. If it fails during a mode switch, the mode switch is aborted but the server keeps running. It is assumed that if the command fails, the clock has not been changed.
Option optionstring	This optional entry allows the user to select certain options provided by the drivers. Multiple <code>Option</code> entries may be given. The supported values for <code>optionstring</code> are given in the appropriate X server manual pages.
VideoRam mem	This optional entry specifies the amount of video RAM that is installed on the graphics board. This is measured in kilobytes. In most cases, this is not required because the X server probes the graphics board to determine this quantity.
BIOSBase baseaddress	This optional entry specifies the base address of the video BIOS for the VGA board. This address is usually 0xC0000, which is the default the X servers use. Some systems, particularly those with on-board VGA hardware, have the BIOS located at an alternate address, usually 0xE0000. If your video BIOS is at an address other than 0xC0000, you must specify the base address in the <code>XF86Config</code> file. Note that some X servers don't access the BIOS at all and those that do only use the BIOS when searching for information during the hardware probe phase.

MemBase baseaddress	This optional entry specifies the memory base address of a graphics board's linear frame buffer. This entry is only used by a few X servers, and the interpretation of this base address may be different for different X servers. Refer to the appropriate X server manual page for details.
IOBase baseaddress	This optional entry specifies the IO base address. This entry is only used for a few X servers. Refer to the appropriate X server manual page for details.
DACBase baseaddress	This optional entry specifies the DAC base address. This entry is only used for a few X servers. Refer to the appropriate X server manual page for details.
POSBASE baseaddress	This optional entry specifies the POS base address. This entry is only used for a few X servers. Refer to the appropriate X server manual page for details.
COPBase baseaddress	This optional entry specifies the coprocessor base address. This entry is only used for a few X servers. Refer to the appropriate X server manual page for details.
VGABase baseaddress	This optional entry specifies the VGA memory base address. This entry is only used for a few X servers. Refer to the appropriate X server manual page for details.
Instance number	This optional entry specifies the instance (which indicates if the chip is integrated on the motherboard or on an expansion card). This entry is only used for a few X servers. Refer to the appropriate X server manual page for details.
Speedup selection	This optional entry specifies the selection of speedups to be enabled. This entry is only used for a few X servers. Refer to the appropriate X server manual page for details.
S3MNAdjust MN	This optional entry is specific to the S3 X server. For details, refer to the XF86_S3(1) manual page.
S3MClk clock	This optional entry is specific to the S3 X server. For details, refer to the XF86_S3(1) manual page.
S3RefClock clock	This optional entry is specific to the S3 X server. For details, refer to the XF86_S3(1) manual page.

The `Screen` sections are used to specify which graphics boards and monitors are used with a particular X server and the configuration in which they are to be used. The entries available for this section are

Driver driver-name	Each <code>Screen</code> section must begin with a <code>Driver</code> entry, and the <code>driver-name</code> given in each <code>Screen</code> section must be unique. The <code>driver-name</code> determines which X server (or driver type within an X server when an X server supports more than one head) reads and uses a particular <code>Screen</code> section. The driver names available are <p>Accel Mono SVGA VGA2 VGA16</p> <p><code>Accel</code> is used by all the accelerated X servers (see XF86_Accel(1)). <code>Mono</code> is used by the non-VGA mono drivers in the 2-bit and 4-bit X servers (see XF86_Mono(1) and XF86_VGA16(1)). <code>VGA2</code> and <code>VGA16</code> are used by the VGA drivers in the 2-bit and 4-bit X servers. <code>SVGA</code> is used by the XF86_SVGA X server.</p>
Device device-id	Specifies which graphics device description is to be used.
Monitor monitor-id	Specifies which monitor description is to be used.
ScreenNo scrnum	This optional entry overrides the default screen numbering in a multi-headed configuration. The default numbering is determined by the ordering of the <code>Screen</code> sections in the XF86Config file. To override this, all relevant <code>Screen</code> sections must have this entry specified.

BlankTime time	Sets the inactivity time-out for the blanking phase of the screensaver. <code>time</code> is in minutes, and the default is 10. This is equivalent to the X server's <code>-s</code> flag, and the value can be changed at runtime with <code>xset(1)</code> .
SuspendTime time	Sets the inactivity time-out for the "suspend" phase of the screensaver. <code>time</code> is in minutes, the default is 15, and it can be changed at runtime with <code>xvidtune(1)</code> . This is only suitable for VESA DPMS compatible monitors and is only supported currently by some X servers. The "power_saver" option must be set for this to be enabled.
OffTime time	Sets the inactivity time-out for the "off" phase of the screensaver. <code>time</code> is in minutes, the default is 30, and it can be changed at runtime with <code>xvidtune(1)</code> . This is only suitable for VESA DPMS compatible monitors and is only supported currently by some X servers. The "power_saver" option must be set for this to be enabled.
SubSection Display	This entry is a subsection that is used to specify some display specific parameters. This subsection is terminated by an <code>EndSubSection</code> entry. For some X servers and drivers (those requiring a list of video modes), this subsection is mandatory. For X servers that support multiple display depths, more than one <code>Display</code> subsection can be present. When multiple <code>Display</code> subsections are present, each must have a unique <code>Depth</code> entry. The entries available for the <code>Display</code> subsection are
Depth bpp	This entry is mandatory when more than one <code>Display</code> subsection is present in a <code>Screen</code> section. When only one <code>Display</code> subsection is present, it specifies the default depth where the X server will run. When more than one <code>Display</code> subsection is present, the depth determines which gets used by the X server. The subsection used is the one matching the depth at which the X server is run. Not all X servers (or drivers) support more than one depth. Permitted values for <code>bpp</code> are 8, 15, 16, 24, and 32. Not all X servers (or drivers) support all these values. <code>bpp</code> values of 24 and 32 are treated equivalently by those X servers that support them.
Weight RGB	This optional entry specifies the relative RGB weighting to be used for an X server running at 16bpp. This may also be specified from the command line (see <code>XFree86(1)</code>). Values supported by most 16bpp X servers are 555 and 565. For further details, refer to the appropriate X server manual page.
Virtual xdim ydim	This optional entry specifies the virtual screen resolution to be used. <code>xdim</code> must be a multiple of either 8 or 16 for most color X servers and a multiple of 32 for the monochrome X server. The given value is rounded down if this is not the case. For most X servers, video modes that are too large for the specified virtual size are rejected. If this entry is not present, the virtual screen resolution is set to accommodate all the valid video modes given in the <code>Modes</code> entry. Some X servers do not support this entry. Refer to the appropriate X server manual pages for details.
ViewPort x0 y0	This optional entry sets the upper-left corner of the initial display. This is only relevant when the virtual screen resolution is different from the resolution of the initial video mode. If this entry is not given, then the initial display is centered in the virtual display area.
Modes modename ...	This entry is mandatory for most X servers, and it specifies the list of video modes to use. The video mode names must correspond to those specified in the appropriate <code>Monitor</code> section. Most X servers delete modes from this list that don't satisfy various requirements. The first valid mode in this list is the default display mode for startup. The list of valid modes is converted internally into a circular list. It is possible to switch to the next mode with <code>Ctrl+Alt+Keypad Plus</code> and to the previous mode with <code>Ctrl+Alt+Keypad Minus</code> .
InvertVCLK modename 0 1	This optional entry is specific to the S3 server only. It can be used to change the default VCLK invert/non-invert state for individual modes. If "modename 0" is "", the setting applies to all modes unless overridden by later entries.

EarlySC modename 0 1	This optional entry is specific to the S3 server only. It can be used to change the default EarlySC setting for individual modes. This setting can affect screen wrapping. If "modename" is "", the setting applies to all modes unless overridden by later entries.
BlankDelay modename value1 value2	This optional entry is specific to the S3 server only. It can be used to change the default blank delay settings for individual modes. This can affect screen wrapping. value1 and value2 must be integers in the range 0–7. If "modename" is "", the setting applies to all modes unless overridden by later entries.
Visual visual -name	This optional entry sets the default root visual type. This can also be specified from the command line (see Xserver(1)). The visual types available for 8bpp X servers are (default is PseudoColor): StaticGray GrayScale StaticColor PseudoColor TrueColor DirectColor The visual type available for the 16bpp and 32bpp X servers is TrueColor. The visual type available for the 1bpp X server is StaticGray. The visual types available for the 4bpp X server are (default is PseudoColor): StaticGray GrayScale StaticColor PseudoColor
Option optionstring	This optional entry allows the user to select certain options provided by the drivers. Multiple Option entries can be given. The supported values for option-string are given in the appropriate X server manual pages.
Black red green blue	This optional entry allows the "black" color to be specified. This is only supported with the VGA2 driver in the XF86_Mono server (for details, see XF86_Mono(1)).
White red green blue	This optional entry allows the "white" color to be specified. This is only supported with the VGA2 driver in the XF86_Mono server (for details, see XF86_Mono(1)).

For an example of an XF86Config file, see the file installed as <XRoot>/lib/X11/XF86Config.eg.

FILES

/etc/XF86Config
 <XRoot>/lib/X11/XF86Config.hostname <XRoot>/lib/X11/XF86Config

Note that <XRoot> refers to the root of the X11 install tree.

Games

intro

`intro`—Introduction to games.

DESCRIPTION

This chapter describes all the games and funny little programs available on the system.

AUTHORS

Look at the header of the manual page for the authors and copyright conditions. Note that these can be different from page to page!

Linux, 24 July 1993

banner

`banner`—Print large banner on printer.

SYNOPSIS

```
/usr/games/banner [ -wn ] message ...
```

DESCRIPTION

`banner` prints a large, high-quality banner on the standard output. If the message is omitted, it prompts for and reads one line of its standard input. If `-w` is given, the output is scrunched down from a width of 132 to `n`, suitable for a narrow terminal. If `n` is omitted, it defaults to 80.

The output should be printed on a hard-copy device, up to 132 columns wide, with no breaks between the pages. The volume is great enough that you might want a printer or a fast hard-copy terminal, but if you are patient, a decwriter or other 300 baud terminal will do.

BUGS

Several ASCII characters are not defined, notably `<`, `>`, `[`, `]`, `\`, `^`, `_`, `{`, `}`, `|`, and ```. Also, the characters `"`, `'`, and `&` are funny-looking (but in a useful way).

The `-w` option is implemented by skipping some rows and columns. The smaller it gets, the grainier the output. Sometimes it runs letters together.

Part VII:

Miscellaneous

intro

intro—Introduction to miscellany section.

DESCRIPTION

This chapter describes miscellaneous things such as `nroff` macro packages, tables, C header files, the file hierarchy, general concepts, and other things that don't fit anywhere else.

AUTHORS

Look at the header of the manual page for the authors and copyright conditions. Note that these can be different from page to page!

Linux, 23 April 1993

ascii

ascii—The ASCII character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The following table contains the 128 ASCII characters.

C program `\X` escapes are noted.

<i>Oct</i>	<i>Dec</i>	<i>Hex</i>	<i>Char</i>	<i>Oct</i>	<i>Dec</i>	<i>Hex</i>	<i>Char</i>
000	0	00	NUL <code>\0</code>	100	64	40	@
001	1	01	SOH	101	65	41	A
002	2	02	STX	102	66	42	B
003	3	03	ETX	103	67	43	C
004	4	04	EOT	104	68	44	D

Linux

bootparam

`bootparam`—Introduction to boot-time parameters of the Linux kernel.

DESCRIPTION

The Linux kernel accepts certain command-line options or boot-time parameters at the moment it is started. In general, this is used to supply the kernel with information about hardware parameters that the kernel would not be able to determine on its own, or to avoid or override the values that the kernel would otherwise detect.

When the kernel is booted directly by the BIOS (say, from a floppy to which you copied a kernel using `cp zImage /dev/fd0`), you have no opportunity to specify any parameters. To take advantage of this possibility, you have to use software that is able to pass parameters, such as LILO or loadlin. For a few parameters, one can also modify the kernel image itself, using `rdev`; see `rdev(8)` for further details.

The LILO program (LInux LOader) written by Werner Almesberger is the most commonly used. It has the ability to boot various kernels and stores the configuration information in a plain text file. (See `lilo(8)` and `lilo.conf(5)`.) LILO can boot DOS, OS/2, Linux, FreeBSD, and so on and is quite flexible.

The other commonly used Linux loader is loadlin, which is a DOS program that has the capability to launch a Linux kernel from the DOS prompt (with boot args) assuming that certain resources are available. This is good for people who want to launch Linux from DOS.

It is also very useful if you have certain hardware that relies on the supplied DOS driver to put the hardware into a known state. A common example is SoundBlaster-compatible sound cards that require the DOS driver to twiddle a few mystical registers to put the card into a SB-compatible mode. Booting DOS with the supplied driver and then loading Linux from the DOS prompt with loadlin avoids the reset of the card that happens if one reboots instead.

THE ARGUMENT LIST

Most of the boot args take the form of

```
name[=val ue_1][,val ue_2]...[,val ue_11]
```

`name` is a unique keyword that is used to identify what part of the kernel the associated values (if any) are to be given to.

Multiple boot args are just a space-separated list of the preceding format. Note the limit of 11 is real because the present code handles only 11 comma-separated parameters per keyword. (However, you can reuse the same keyword with up to an additional 11 parameters in unusually complicated situations, assuming the setup function supports it.)

Most of the sorting occurs in `linux/init/main.c`. First, the kernel checks to see if the argument is any of the special arguments `root=`, `ro`, `rw`, or `debug`. The meaning of these special arguments is described later in the document.

Then, it walks a list of setup functions (contained in the `bootsetups` array) to see if the specified argument string (such as `foo`) is associated with a setup function (`foo_setup()`) for a particular device or part of the kernel. If you passed the kernel the line `foo=3,4,5,6`, then the kernel searches the `bootsetups` array to see if `foo` is registered. If it is, it calls the setup function associated with `foo` (`foo_setup()`) and hands it the arguments 3, 4, 5, and 6 as given on the kernel command line.

Anything of the form `foo=bar` that is not accepted as a setup function as described is then interpreted as an environment variable to be set. A (useless?) example is to use `TERM=vt100` as a boot argument.

Any remaining arguments that were not picked up by the kernel and were not interpreted as environment variables are then passed onto process one, which is usually the `init` program. The most common argument that is passed to the `init` process is the word `single`, which instructs `init` to boot the computer in single-user mode and not launch all the usual daemons. Check the manual page for the version of `init` installed on your system to see what arguments it accepts.

GENERAL NON-DEVICE-SPECIFIC BOOT ARGS

`no387`

Some i387 coprocessor chips have bugs that show up when used in 32-bit protected mode.

For example, some of the early ULSI-387 chips cause solid lockups while performing floating-point calculations. Using the `'no387'` boot arg causes Linux to ignore the maths coprocessor even if you have one. Of course, you must then have your kernel compiled with math emulation support!

`no-hlt`

Some of the early i486DX-100 chips have a problem with the `hlt` instruction in that they can't reliably return to operating mode after this instruction is used. Using the `'no-hlt'` instruction tells Linux to just run an infinite loop when there is nothing else to do and to not halt the CPU. This allows people with these broken chips to use Linux.

`root=...`

This argument tells the kernel what device is to be used as the root filesystem while booting. The default of this setting is determined at compile time and usually is the value of the root device of the system that the kernel was built on. To override this value and select the second floppy drive as the root device, one uses `'root=/dev/fd1'`. (The root device can also be set using `rdev(8)`.)

The root device can be specified symbolically or numerically. A symbolic specification has the form `/dev/XXYN`, where `XX` designates the device type (`hd` for ST-506-compatible hard disk with `Y` in `a-h`; `sd` for SCSI-compatible disk with `Y` in `a-e`; `xd` for XT-compatible disk with `Y` either `a` or `b`; `fd` for floppy disk with `Y` the floppy drive number—`fd0` is the DOS A: drive and `fd1` is B:), `Y` is the driver letter or number, and `N` is the number of the partition on this device (absent in the case of floppies).

Note that this has nothing to do with the designation of these devices on your filesystem. The `/dev/` part is purely conventional.

The more awkward and less portable numeric specification of the previous possible root devices in major/minor format is also accepted. (For example, `/dev/sda3` is major 8, minor 3, so you can use `root=0x803` as an alternative.)

`ro` and `rw`

The `ro` option tells the kernel to mount the root filesystem as `readonly` so that filesystem consistency check programs (`fsck`) can do their work on a quiescent file system. No processes can write to files on the filesystem in question until it is remounted as read/write capable, such as by `mount -w -n -o remount /`. (See also `mount(8)`.)

The `rw` option tells the kernel to mount the root filesystem read/write. This is the default.

The choice between read-only and read/write can also be set using `rdev(8)`.

`debug`

Kernel messages are handed off to the kernel log daemon `klogd` so that they can be logged to disk. Messages with a priority above `console_loglevel` are also printed on the console. (For these levels, see `<linux/kernel.h>`.) By default, this variable is set to log anything more important than debug messages. This boot argument causes the kernel to also print the messages of `DEBUG` priority. The console log level can also be set at runtime via an option to `klogd`. See `klogd(8)`.

`reserve=...`

This is used to protect I/O port regions from probes. The form of the command is

```
reserve=i obase,extent[,i obase,extent]...
```

In some machines, it might be necessary to prevent device drivers from checking for devices (auto-probing) in a specific region. This may be because of hardware that reacts badly to the probing, hardware that would be mistakenly identified, or hardware you don't want the kernel to initialize.

The `reserve` boot-time argument specifies an I/O port region that shouldn't be probed. A device driver does not probe a reserved region unless another boot argument explicitly specifies that it do so.

For example, the boot line

```
reserve=0x300,32 blah=0x300
```

keeps all device drivers except the driver for `blah` from probing `0x300-0x31f`.

```
ramdisk=...
```

This option is obsolete since Linux 1.3.48 or so. It specifies the size in kilobytes of the optional RAM disk device. For example, if one wants to have a root filesystem on a 1.44MB floppy loaded into the RAM disk device, they use

```
ramdisk=1440
```

This option is set at compile time (default is no RAM disk), and can be modified using `rdev(8)`.

```
mem=...
```

The BIOS call defined in the PC specification that returns the amount of installed memory was only designed to be able to report up to 64MB. Linux uses this BIOS call at boot to determine how much memory is installed. If you have more than 64MB of RAM installed, you can use this boot arg to tell Linux how much memory you have. The value is in decimal or hexadecimal (prefix `0x`), and the suffixes `k` (times 1024) or `M` (times 1048576) can be used. The following quote from Linus describes the use of the `mem=` parameter:

“The kernel will accept any `mem=xx` parameter you give it, and if it turns out that you lied to it, it will crash horribly sooner or later. The parameter indicates the highest addressable RAM address, so `'mem=0x1000000'` means you have 16MB of memory, for example. For a 96MB machine this would be `mem=0x6000000`.

NOTE: Some machines might use the top of memory for BIOS caching or whatever, so you might not actually have up to the full 96MB addressable. The reverse is also true: Some chipsets will map the physical memory that is covered by the BIOS area into the area just past the top of memory, so the top-of-mem might actually be 96MB + 384KB, for example. If you tell Linux that it has more memory than it actually does have, bad things will happen: maybe not at once, but surely eventually.”

```
reboot=warm
```

Since 2.0.22, a reboot is by default a cold reboot. This command-line option changes back to the old default, a warm reboot.

BOOT ARGUMENTS FOR SCSI DEVICES

General notation for this section:

`iobase`—the first I/O port that the SCSI host occupies. These are specified in hexadecimal notation and usually lie in the range from `0x200` to `0x3ff`.

`irq`—the hardware interrupt that the card is configured to use. Valid values are dependent on the card in question but are usually 5, 7, 9, 10, 11, 12, and 15. The other values are usually used for common peripherals such as IDE hard disks, floppies, serial ports, and so on.

`scsi-id`—the ID that the host adapter uses to identify itself on the SCSI bus. Only some host adapters allow you to change this value because most have it permanently specified internally. The usual default value is 7, but the Seagate and Future Domain TMC-950 boards use 6.

`parity`—whether the SCSI host adapter expects the attached devices to supply a parity value with all information exchanges. Specifying a `1` indicates parity checking is enabled, and a `0` disables parity checking. Again, not all adapters support selection of parity behavior as a boot argument.

```
max_scsi_luns=...
```

A SCSI device can have a number of subdevices contained within itself. The most common example is one of the new SCSI CD-ROMs that handle more than one disk at a time. Each CD is addressed as a Logical Unit Number (LUN) of that particular device. Most devices, such as hard disks and tape drives, are only one device and are assigned to LUN 0.

Some poorly designed SCSI devices cannot handle being probed for LUNs not equal to 0. Therefore, if the compile-time flag `CONFIG SCSI MULTI LUN` is not set, newer kernels by default only probe LUN 0.

To specify the number of probed LUNs at boot, one enters `max_scsi_luns=n` as a boot arg, where `n` is a number between 1 and 8. To avoid problems as described, one uses `n=1` to avoid upsetting such broken devices.

SCSI TAPE CONFIGURATION

Some boot-time configuration of the SCSI tape driver can be achieved with the following:

```
st=buf_si ze[,wri te_threshold[,max_bufs]]
```

The first two numbers are specified in units of kilobytes. The default `buf_si ze` is 32KB, and the maximum size that can be specified is a ridiculous 16384KB. The `wri te_threshold` is the value at which the buffer is committed to tape with a default value of 30KB. The maximum number of buffers varies with the number of drives detected and has a default of two. A sample usage is

```
st=32,30,2
```

Full details can be found in the `README.st` file that is in the `scsi` directory of the kernel source tree.

ADAPTEC AHA151X, AHA152X, AIC6260, AIC6360, SB16-SCSI CONFIGURATION

The `aha` numbers refer to cards and the `aic` numbers refer to the actual SCSI chip on these types of cards, including the SoundBlaster-16 SCSI.

The probe code for these SCSI hosts looks for an installed BIOS, and if none is present, the probe will not find your card. Then you must use a boot arg of the form:

```
aha152x=i obase[,i rq[,scsi -i d[,reconnect[,pari ty]]]]
```

If the driver was compiled with debugging enabled, a sixth value can be specified to set the debug level.

All the parameters are as described at the top of this section, and the `reconnect` value allows device disconnect/reconnect if a nonzero value is used. A sample usage is as follows:

```
aha152x=0x340,11,7,1
```

Note that the parameters must be specified in order, meaning that if you want to specify a parity setting, then you must specify an `i obase`, `i rq`, `scsi -i d`, and `reconnect` value as well.

ADAPTEC AHA154X CONFIGURATION

The `aha1542` series cards have an `i82077` floppy controller on board, whereas the `aha1540` series cards do not. These are bus-mastering cards and have parameters to set the “fairness” that is used to share the bus with other devices. The boot arg looks like the following:

```
aha1542=i obase[,buson,busoff[,dmaspeed]]
```

Valid `i obase` values are usually one of `0x130`, `0x134`, `0x230`, `0x234`, `0x330`, or `0x334`. Clone cards may permit other values.

The `buson` and `busoff` values refer to the number of microseconds that the card dominates the ISA bus. The defaults are `11us on` and `4us off` so that other cards (such as an ISA LANCE Ethernet card) have a chance to get access to the ISA bus.

The `dmaspeed` value refers to the rate (in MB/s) at which the DMA (Direct Memory Access) transfers proceed. The default is 5MB/s. Newer revision cards allow you to select this value as part of the soft-configuration; older cards use jumpers. You can use values up to 10MB/s, assuming that your motherboard is capable of handling it. Experiment with caution if using values over 5MB/s.

ADAPTEC AHA274X, AHA284X, AIC7XXX CONFIGURATION

These boards can accept an argument of the form:

```
aic7xxx=extended,no_reset
```

The `extended` value, if nonzero, indicates that extended translation for large disks is enabled. The `no_reset` value, if nonzero, tells the driver not to reset the SCSI bus when setting up the host adapter at boot.

BUSLOGIC SCSI HOSTS CONFIGURATION (buslogic=)

At present, the `buslogic` driver accepts only one parameter, the I/O base. It expects that to be one of the following valid values: `0x130`, `0x134`, `0x230`, `0x234`, `0x330`, or `0x334`.

FUTURE DOMAIN TMC-8XX, TMC-950 CONFIGURATION

If your card is not detected at boot time, you must use a boot arg of the form

```
tmc8xx=mem_base,irq
```

The `mem_base` value is the value of the memory-mapped I/O region that the card uses. This is usually one of the following values: `0xc8000`, `0xca000`, `0xcc000`, `0xce000`, `0xdc000`, or `0xde000`.

PRO AUDIO SPECTRUM CONFIGURATION

The PAS16 uses an NC5380 SCSI chip, and newer models support jumperless configuration. The boot arg is of the form

```
pas16=iobase,irq
```

The only difference is that you can specify an IRQ value of 255, which tells the driver to work without using interrupts, albeit at a performance loss. The `iobase` is usually `0x388`.

SEAGATE ST-0X CONFIGURATION

If your card is not detected at boot time, you must use a boot arg of the form

```
st0x=mem_base,irq
```

The `mem_base` value is the value of the memory-mapped I/O region that the card uses. This is usually one of the following values: `0xc8000`, `0xca000`, `0xcc000`, `0xce000`, `0xdc000`, or `0xde000`.

TRANTOR T128 CONFIGURATION

These cards are also based on the NCR5380 chip and accept the following options:

```
t128=mem_base,irq
```

The valid values for `mem_base` are as follows: `0xcc000`, `0xc8000`, `0xdc000`, and `0xd8000`.

CARDS THAT DON'T ACCEPT BOOT ARGS

At present, the following SCSI cards do not make use of any boot-time parameters. In some cases, you can hard-wire values by directly editing the driver itself, if required.

Always IN2000, Adaptec aha1740, EATA-DMA, EATA-PIO, Future Domain 16xx, NCR5380 (generic), NCR53c7xx to NCR53c8xx, Qlogic, Ultrastor (including u24f), and Western Digital wd7000.

HARD DISKS

IDE DISK/CD-ROM DRIVER PARAMETERS

The IDE driver accepts a number of parameters, which range from disk geometry specifications to support for broken controller chips. Drive specific options are specified by using `hdX=` with `X` in a-h.

Non-drive-specific options are specified with the prefix `hd=`. Note that using a drive-specific prefix for a non-drive-specific option will still work, and the option will just be applied as expected.

Also note that `hd=` can be used to refer to the next unspecified drive in the (a, ..., h) sequence. For the following discussions, the `hd=` option will be cited for brevity. See the file `README.ide` in `linux/drivers/block` for more details.

THE `hd=cyls,heads,sects[,wpcom[,irq]]` OPTIONS

These options are used to specify the physical geometry of the disk. Only the first three values are required. The cylinder, head, and sectors values are those used by `fdisk`. The write precompensation value is ignored for IDE disks. The IRQ value specified is the IRQ used for the interface that the drive resides on and is not really a drive-specific parameter.

THE `hd=serialize` OPTION

The dual IDE interface CMD-640 chip is broken as designed such that when drives on the secondary interface are used at the same time as drives on the primary interface, it will corrupt your data. Using this option tells the driver to make sure that both interfaces are never used at the same time.

THE `hd=dtc2278` OPTION

This option tells the driver that you have a DTC-2278D IDE interface. The driver then tries to do DTC-specific operations to enable the second interface and to enable faster transfer modes.

THE `hd=noprobe` OPTION

Do not probe for this drive. The following line

```
hdb=noprobe hdb=1166,7,17
```

disables the probe but still specifies the drive geometry so that it is registered as a valid block device and hence usable.

THE `hd=nowerr` OPTION

Some drives apparently have the `WRERR` STAT bit stuck on permanently. This enables a work-around for these broken devices.

THE `hd=cdrom` OPTION

This tells the IDE driver that there is an ATAPI compatible CD-ROM attached in place of a normal IDE hard disk. In most cases, the CD-ROM is identified automatically, but if it isn't, then this might help.

STANDARD ST-506 DISK DRIVER OPTIONS (`hd=`)

The standard disk driver can accept geometry arguments for the disks similar to the IDE driver. Note however that it only expects three values (C/H/S); any more or any less and it will silently ignore you. Also, it only accepts `hd=` as an argument; `hda=` and so on are not valid here. The format is as follows:

```
hd=cyl s,heads,sects
```

If there are two disks installed, the preceding line is repeated with the geometry parameters of the second disk.

XT DISK DRIVER OPTIONS (`xd=`)

If you are unfortunate enough to be using one of these old 8-bit cards that move data at a whopping 125KB/s, then here is the scoop. If the card is not recognized, you must use a boot arg of the form

```
xd=type,irq,iobase,dma_chan
```

The `type` value specifies the particular manufacturer of the card, and you use one of the following: 0=generic, 1=DTC, 2, 3, 4=Western Digital, 5, 6, 7=Seagate, or 8=OMTI. The only difference between multiple types from the same manufacturer is the BIOS string used for detection, which is not used if the type is specified.

The `xd_setup()` function does no checking on the values and assumes that you entered all four values. Don't disappoint it. Here is a sample usage for a WD1002 controller with the BIOS disabled or removed, using the default XT controller parameters:

```
xd=2,5,0x320,3
```

CD-ROMS (NON-SCSI/ATAPI/IDE)

THE AZTECH INTERFACE

The syntax for this type of card is

```
aztcd=i obase[ ,magi c_number]
```

If you set the `magi c_number` to `0x79`, the driver will run anyway in the event of an unknown firmware version. All other values are ignored.

THE CDU-31A AND CDU-33A SONY INTERFACE

This CD-ROM interface is found on some of the Pro Audio Spectrum sound cards and other Sony supplied interface cards.

The syntax is as follows:

```
cd31a=i obase,[i rq[ ,i s_pas_card]]
```

Specifying an IRQ value of `0` tells the driver that hardware interrupts aren't supported (as on some PAS cards). If your card supports interrupts, you should use them because they cut down on the CPU usage of the driver.

The `i s_pas_card` should be entered as `PAS` if using a Pro Audio Spectrum card; otherwise, it should not be specified at all.

THE CDU-535 SONY INTERFACE

The syntax for this CD-ROM interface is

```
sonycd535=i obase[ ,i rq]
```

A `0` can be used for the I/O base as a placeholder if you want to specify an IRQ value.

THE GOLDSTAR INTERFACE

The syntax for this CD-ROM interface is

```
gscd=i obase
```

THE MITSUMI STANDARD INTERFACE

The syntax for this CD-ROM interface is

```
mcd=i obase,[i rq[ ,wai t_val ue]]
```

The `wai t_val ue` is used as an internal time-out value for people who are having problems with their drive and may or may not be implemented depending on a compile-time `#define`. The Mitsumi FX400 is an IDE/ATAPI CD-ROM player and does not use the `mcd` driver.

THE MITSUMI XA/MULTISESSION INTERFACE (`mcdx=`)

At present, this experimental driver has a setup function, but no parameters are implemented (as of 1.3.15). This is for the same hardware as previously described, but the driver has extended features.

THE OPTICS STORAGE INTERFACE

The syntax for this type of card is

```
optcd=i obase
```

THE PHILLIPS CM206 INTERFACE

The syntax for this type of card is

```
cm206=[i obase][ ,i rq]
```

The driver assumes numbers between 3 and 11 are IRQ values and numbers between `0x300` and `0x370` are I/O ports, so you can specify one, or both numbers, in any order. It also accepts `cm206=auto` to enable autoprobng.

THE SANYO INTERFACE

The syntax for this type of card is

```
sjcd=i obase[,i rq[,dma_channel ]]
```

THE SOUNDBLASTER PRO INTERFACE

The syntax for this type of card is

```
sbpcd=i obase,type
```

`type` is one of the following (case-sensitive) strings: `SoundBlaster`, `LaserMate`, or `SPEA`. The I/O base is that of the CD-ROM interface and not that of the sound portion of the card.

ETHERNET DEVICES

Different drivers use different parameters, but they all at least share having an IRQ, an I/O port base value, and a name. In its most generic form, it looks something like this:

```
ether=i rq,i obase[,param_1[,param_2,...param_8]],name
```

The first non-numeric argument is taken as the name. The `param_n` values (if applicable) usually have different meanings for each different card or driver. Typical `param_n` values are used to specify things such as shared memory address, interface selection, DMA channel, and the like.

The most common use of this parameter is to force probing for a second ethercard because the default is to only probe for one. This can be accomplished with a simple

```
ether=0,0,eth1
```

Note that the values of 0 for the IRQ and I/O base in the example tell the drivers to autoprobe.

The Ethernet How To has extensive documentation on using multiple cards and on the card-specific or driver-specific implementation of the `param_n` values where used. Interested readers should refer to the section in that document on their particular card.

THE FLOPPY DISK DRIVER

There are many floppy driver options, and they are all listed in `README.fd` in `linux/drivers/block`. This information is taken directly from that file.

```
floppy=mask,allowed_drive_mask
```

Sets the bitmask of allowed drives to `mask`. By default, only units 0 and 1 of each floppy controller are allowed. This is done because certain non-standard hardware (ASUS PCI motherboards) mess up the keyboard when accessing units 2 or 3. This option is somewhat obsolete because of the `cmos` option.

```
floppy=all drives
```

Sets the bitmask of allowed drives to all drives. Use this if you have more than two drives connected to a floppy controller.

```
floppy=asus_pci
```

Sets the bitmask to allow only units 0 and 1 (the default).

```
floppy=daring
```

Tells the floppy driver that you have a well-behaved floppy controller. This allows more efficient and smoother operation but may fail on certain controllers. This can speed up certain operations.

```
floppy=0,daring
```

Tells the floppy driver that your floppy controller should be used with caution.

`floppy=one_fdc`

Tells the floppy driver that you have only one floppy controller (default).

`floppy=two_fdc` OR `floppy=address,two_fdc`

Tells the floppy driver that you have two floppy controllers. The second floppy controller is assumed to be at address. If address is not given, `0x370` is assumed.

`floppy=thinkpad`

Tells the floppy driver that you have a Thinkpad. Thinkpads use an inverted convention for the disk change line.

`floppy=0,thinkpad`

Tells the floppy driver that you don't have a Thinkpad.

`floppy=drive,type,cmos`

Sets the `cmos` type of drive to `type`. Additionally, this drive is allowed in the bitmask. This is useful if you have more than two floppy drives (only two can be described in the physical `cmos`), or if your BIOS uses non-standard `cmos` types. Setting the `cmos` to `0` for the first two drives (default) makes the floppy driver read the physical `cmos` for those drives.

`floppy=unexpected_interrupts`

Print a warning message when an unexpected interrupt is received (default behavior)

`floppy=no_unexpected_interrupts` OR `floppy=L40SX`

Don't print a message when an unexpected interrupt is received. This is needed on IBM L40SX laptops in certain video modes. (There seems to be an interaction between video and floppy. The unexpected interrupts only affect performance and can safely be ignored.)

THE SOUND DRIVER

The sound driver can also accept boot args to override the compiled in values. This is not recommended because it is rather complex. It is described in the `Readme.Linux` file in `linux/drivers/sound`. It accepts a boot arg of the form

```
sound=devi ce1[,devi ce2[,devi ce3...[,devi ce11]]]
```

Each `devi ceN` value is of the format `0xTaaa d` and the bytes are used as follows:

T—device type: 1=FM, 2=SB, 3=PAS, 4=GUS, 5=MPU401, 6=SB16, and 7=SB16-MPU401

aaa—I/O address in hex

l—interrupt line in hex (10=a, 11=b, ...)

d—DMA channel

As you can see, it gets pretty messy, and you are better off to compile in your own personal values as recommended. Using a boot arg of `sound=0` disables the sound driver entirely.

THE BUS MOUSE DRIVER (`bmouse=`)

The `bmouse` driver only accepts one parameter, the hardware IRQ value to be used.

AUTHORS

Linus Torvalds (and many others)

groff_me

groff_me—troff macros for formatting papers.

SYNOPSIS

```
groff_me [ options ] file ...
troff_me [ options ] file ...
```

DESCRIPTION

This manual page describes the GNU version of the `_me` macros, which is part of the `groff` document formatting system. This version can be used with both GNU `troff` and UNIX `troff`. This package of `troff` macro definitions provides a canned formatting facility for technical papers in various formats.

The macro requests are defined as follows. Many `troff` requests are unsafe in conjunction with this package; however, these requests can be used with impunity after the first `.pp`:

<code>.bp</code>	Begin new page
<code>.br</code>	Break output line here
<code>.sp n</code>	Insert <code>n</code> spacing lines
<code>.ls n</code>	Line spacing; <code>n=1</code> single, <code>n=2</code> double space
<code>.na</code>	No alignment of right margin
<code>.ce n</code>	Center next <code>n</code> lines
<code>.ul n</code>	Underline next <code>n</code> lines

Output of the `pic`, `eqn`, `refer`, and `tbl` preprocessors is acceptable as input.

FILES

`/usr/lib/groff/tmac/tmac.e`

SEE ALSO

`groff(1)`, `gtroff(1)`, `_me` Reference Manual, Eric P. Allman, Writing Papers with Groff Using `_me`

REQUESTS

This list is incomplete; see the `_me` Reference Manual for interesting details.

<i>Request</i>	<i>Initial Value</i>	<i>Cause Break</i>	<i>Explanation</i>
<code>.(c</code>	-	Yes	Begin centered block.
<code>.(d</code>	-	No	Begin delayed text.
<code>.(f</code>	-	No	Begin footnote.
<code>.(l</code>	-	Yes	Begin list.
<code>.(q</code>	-	Yes	Begin major quote.
<code>.(x x</code>	-	No	Begin indexed item in index <code>x</code> .
<code>.(z</code>	-	No	Begin floating keep.
<code>.)c</code>	-	Yes	End centered block.
<code>.)d</code>	-	Yes	End delayed text.
<code>.)f</code>	-	Yes	End footnote.
<code>.)l</code>	-	Yes	End list.
<code>.)q</code>	-	Yes	End major quote.

continues

<i>Request</i>	<i>Initial Value</i>	<i>Cause Break</i>	<i>Explanation</i>
.)x	-	Yes	End index item.
.)z	-	Yes	End floating keep.
.++ m H	-	No	Define paper section. m defines the part of the paper and can be C (chapter), A (appendix), P (preliminary, such as abstract, table of contents, and so on), B (bibliography), RC (chapters renumbered from page one each chapter), or RA (appendix renumbered from page one).
.+c T	-	Yes	Begin chapter (or appendix and so on as set by .++). T is the chapter title.
.1c	1	Yes	One column format on a new page.
.2c	1	Yes	Two column format. Equation number is y.
.EN	-	Yes	Space after equation produced by eqn or neqn.
.EQ x y	-	Yes	Precede equation; break out and add space. The optional argument x may be I to indent equation (default), L to left-adjust the equation, or C to center the equation.
.GE	-	Yes	End gremlin picture.
.GS	-	Yes	Begin gremlin picture.
.PE	-	Yes	End pic picture.
.PS	-	Yes	Begin pic picture.
.TE	-	Yes	End table.
.TH	-	Yes	End heading section of table.
.TS x	-	Yes	Begin table; if x is H, table has repeated heading.
.b x	No	No	Print x in boldface; if no argument switch to boldface.
.ba +n	0	Yes	Augments the base indent by n. This indent is used to set the indent on regular text (like paragraphs).
.bc	No	Yes	Begin new column.
.bi x	No	No	Print x in bold italics (no fill only).
.bu	-	Yes	Begin bulleted paragraph.
.bx x	No	No	Print x in a box (no fill only).
.ef 'x'y'z'	""	No	Set even footer to x y z.
.eh 'x'y'z'	""	No	Set even header to x y z.
.fo 'x'y'z'	""	No	Set footer to x y z.
.hx	-	No	Suppress headers and footers on next page.
.he 'x'y'z'	""	No	Set header to x y z.
.hl	-	Yes	Draw a horizontal line.
.i x	No	No	Italicize x; if x is missing, italic text follows.
.ip x y	No	Yes	Start indented paragraph with hanging tag x. Indentation is y ens (default is 5).

<i>Request</i>	<i>Initial Value</i>	<i>Cause Break</i>	<i>Explanation</i>
.lp	Yes	Yes	Start left-blocked paragraph.
.np	1	Yes	Start numbered paragraph.
.of 'x'y'z'	""	No	Set odd footer to x y z.
.oh 'x'y'z'	""	No	Set odd header to x y z.
.pd	-	Yes	Print delayed text.
.pp	No	Yes	Begin paragraph. First line indented.
.r	Yes	No	Roman text follows.
.re	-	No	Reset tabs to default values.
.sh n x	-	Yes	Section head follows; font is automatically bold. n is level of section. x is title of section.
.sk	No	No	Leave the next page blank. Only one page is remembered ahead.
.sm x	-	No	Set x in a smaller point size.
.sz +n	10p	No	Augment the point size by n points.
.tp	No	Yes	Begin title page.
.u x	-	No	Underline argument (even in troff) (nofill only).
.uh	-	Yes	Like .sh but unnumbered.
.xp x	-	No	Print index x.

Groff Version 1.09, 6 August 1992

groff_mm

groff_mm—groff mm macros.

SYNOPSIS

```
groff_mgm [ options... ] [ files... ]
```

DESCRIPTION

The groff mm macros are intended to be compatible with the DWB mm macros with the following limitations:

No letter macros are implemented (yet).

No Bell Labs localisms are implemented.

The macros OK and PM are not implemented.

groff mm does not support cut marks.

mgm is intended to be international. Therefore, it is possible to write short national macro-files that change all English text to the preferred language. Use mgmse as an example.

groff mm has several extensions:

1C [1]

APP name text

Begin one column processing. A 1 as argument disables the page break.

Begin an appendix with the name name. Automatic naming occurs if name is "". The appendix starts with A if auto is used. A new page is ejected, and a header is also produced if the number variable A_{ph} is non-zero. This is the default. The appendix always appear in the list of contents with the correct page number. The name APPENDIX can be changed by setting the string App to the desired text.

APPSK name pages text	Same as <code>.APP</code> , but the page number is incremented with <code>pages</code> . This is used when diagrams or other non-formatted documents are included as appendixes.
B1	Begin box (as the <code>ms</code> macro) Draws a box around the text.
B2	End box. Finish the box.
BVL	Start of broken variable-item list. Like <code>VL</code> but text begins always at the next line.
COVER [arg]	<code>COVER</code> begins a coversheet definition. It is important that <code>.COVER</code> appears before any normal text. <code>.COVER</code> uses <code>arg</code> to build the filename <code>/usr/lib/groff/tmac/mm/arg.cov</code> . Therefore, it is possible to create unlimited types of coversheets. <code>ms.cov</code> is supposed to look like the <code>ms</code> coversheet. <code>.COVER</code> requires a <code>.COVEND</code> at the end of the cover definition. Always use this order of the cover macros: <pre>.COVER .TL .AF .AU .AT .AS .AE .COVEND</pre>
COVEND	However, only <code>.TL</code> and <code>.AU</code> are required. This finishes the cover description and prints the cover page. It is defined in the cover file.
GETHN refname [varname]	Includes the header number where the corresponding <code>SETR refname</code> was placed. Will be <code>X.X.X</code> in pass 1. See <code>INITR</code> . If <code>varname</code> is used, <code>GETHN</code> sets the string variable <code>varname</code> to the header number.
GETPN refname [varname]	Includes the page number where the corresponding <code>SETR refname</code> was placed. Will be <code>9999</code> in pass 1. See <code>INITR</code> . If <code>varname</code> is used, <code>GETPN</code> sets the string variable <code>varname</code> to the page number.
GETR refname	Combines <code>GETHN</code> and <code>GETPN</code> with the text 'chapter' and ', page'. The string <code>Qrf</code> contains the text for reference: <code>.ds Qrf See chapter *[Qrfh], page *[Qrfp]</code> . <code>Qrf</code> may be changed to support other languages. Strings <code>Qrfh</code> and <code>Qrfp</code> are set by <code>GETR</code> and contain the page and header number.
GETST refname [varname]	Includes the string saved with the second argument to <code>.SETR</code> . Will be dummy string in pass 1. If <code>varname</code> is used, <code>GETST</code> sets the string variable <code>varname</code> to the saved string. See <code>INITR</code> .
INITR filename	Initialize the reference macros. References will be written to <code>filename.tmp</code> and <code>filename.qrf</code> . Requires two passes with <code>groff</code> . The first looks for references and the second includes them. <code>INITR</code> can be used several times, but it is only the first occurrence of <code>INITR</code> that is active. See also <code>SETR</code> , <code>GETPN</code> , and <code>GETHN</code> .
MC column-size [column-separation]	Begin multiple columns. Return to normal with <code>1c</code> .
MT [arg [addressee]]	Memorandum type. The <code>arg</code> is part of a filename in <code>/usr/lib/groff/tmac/mm/*.MT</code> . Memorandum type <code>0</code> through <code>5</code> are supported, including <code>string</code> . <code>addressee</code> just sets a variable, used in the AT&T macros.
MOVE y-pos [x-pos[line-length]]	Move to a position, page offset set to <code>x-pos</code> . If <code>line-length</code> is not given, the difference between the current and new page offset is used. Use <code>PGFORM</code> without arguments to return to normal.

MULB cw1 space1[cw2 space2 [cw3 ...]]

Begin a special multi-column mode. Every column's width must be specified. Also, the space between the columns must be specified. The last column does not need any space definition. MULB starts a diversion and MULE ends the diversion and prints the columns. The unit for width and space is *n*, but MULB accepts all normal unit specifications such as *c* and *i*. MULB operates in a separate environment.

MULN

Begin the next column. This is the only way to switch columns.

MULE

End the multi-column mode and print the columns.

PGFORM [l i n e l e n g t h [p a g e l e n g t h [p a g e o f f s e t [1]]]]

This macro can be used for special formatting, such as PGFORM letterheads. Sets can be used without arguments to reset everything after a MOVE. A line break is done unless the fourth argument is given. This can be used to avoid the page number on the first page while setting new width and length.

l i n e l e n g t h , p a g e l e n g t h **and/or** p a g e o f f s e t .

PGNH

No header is printed on the next page. Used to get rid of the header in letters or other special texts. This macro must be used before any text to inhibit the page header on the first page.

SETR refname [string]

Remember the current header and page number as *refname*. Saves *string* if *string* is defined. *string* is retrieved with .GETST. See INITR.

TAB

Reset tabs to every *5n*. Usually used to reset any previous tab positions.

VERBON [f l a g [p o i n t s i z e [f o n t]]]

Begin verbatim output using Courier font. Usually for printing programs. All characters have equal width. The point size can be changed with the second argument. By specifying the font argument, it is possible to use another font instead of Courier. *flag* controls several special features. It contains the sum of all wanted features:

<i>Value</i>	<i>Description</i>
1	Disable the escape-character (<i>n</i>). This is usually turned on during verbose output.
2	Add an empty line before the verbose text.
4	Add an empty line after the verbose text.
8	Print the verbose text with numbered lines. This adds four digit-sized spaces in the beginning of each line. Finer control is available with the string-variable <i>Verbnm</i> . It contains all arguments to the troff-command <i>.nm</i> , usually 1.
16	Indent the verbose text with five <i>ns</i> . This is controlled by the number-variable <i>Verbin</i> (in units).

VERBOFF

End verbatim output.

New variables in *mgm*:

App

A string containing the word APPENDIX.

Aph

Print an appendix page for every new appendix if this number variable is nonzero. No output will occur if *Aph* is zero, but there

Hps	will always be an appendix entry in the list of contents. Number variable with the heading pre-space level. If the heading level is less than or equal to Hps, then two lines precede the section heading instead of one. Default is first level only. The real amount of lines is controlled by the variables Hps1 and Hps2.
Hps1	This is the number of lines preceding .H when the heading level is greater than Hps. Value is in units, usually 0.5v.
Hps2	This is the number of lines preceding .H when the heading level is less than or equal to Hps. Value is in units, usually 1v.
Lifg	String containing figure.
Litb	String containing table.
Liex	String containing exhibit.
Liec	String containing equation.
Licon	String containing contents.
Lsp	The size of an empty line. Usually 0.5v, but it is 1v if n is set (.nroff).
MO1 - MO12	Strings containing January to December.
Qrf	String containing "See chapter \\ <i>Qrfh</i> , page \\ <i>n</i> [<i>Qrfp</i>].".
Pgps	Controls whether header and footer point size should follow the current setting or just change when the header and footer is defined.

<i>Value</i>	<i>Description</i>
0	Point size will only change to the current setting when .PH, .PF, .OH, .EH, .OF, or .OE is executed.
1	Point size will change after every .S. This is the default.

Sectf	Flag controlling section figures. A nonzero value enables this. See also register N.
Sectp	Flag controlling section page numbers. A nonzero value enables this. See also register N.
.mgm	Always 1.

A file called `locale` or `lang_locale` is read after the initiation of the global variables. It is therefore possible to localize the macros with a company name and so on.

The following standard macros are implemented:

2C	Begin two column processing.
AE	Abstract end.
AF [name of firm]	Author's firm.
AL [type[text-indent [1]]]	Start autoincrement list.
AS [arg [indent]]	Abstract start. Indent is specified in ens, but scaling is allowed.
AST [title]	Abstract title. Default is 'ABSTRACT'.
AT title1 [title2 ...]	Author's title.
AU name [initials [loc [dept [ext [room [arg [arg [arg]]]]]]]]	Author information.
B [bold-text[prev-font-text [...]]]	Begin boldface. No limit on the number of arguments.

MT [arg [addressee]]

End bottom block.

Bold italic. No limit on the number of arguments.

Start bullet list.

Bold roman. No limit on the number of arguments.

Bottom block start.

Display end.

Begin floating display (no nesting allowed).

Dash list start.

Static display start. Can now have unlimited nesting. Also, right-adjusted text and block may be used (R or RB as format).

Equation title. If `refname` is used, then the equation number is saved with `.SETR` and can be retrieved with `.GETST refname`.

Even page footer.

Even page header.

Equation end.

Equation start.

Exhibit title. If `refname` is used, then the exhibit number is saved with `.SETR` and can be retrieved with `.GETST refname`.

Footnote default format.

Footnote end.

Figure title. If `refname` is used, then the figure number is saved with `.SETR` and can be retrieved with `.GETST refname`.

Footnote start. Footnotes in displays is now possible.

Numbered heading.

Set hyphenation character.

Heading mark style.

Unnumbered header.

User-defined heading exit. Called just before printing the header.

User-defined heading exit. Called just before printing the header.

User-defined heading exit. Called just after printing the header.

 Reference list start.
 Produce reference page.
 Reference start.
 Set point size and vertical spacing. If any argument equals P, then the previous value is used. A C means current value, and D means default value. If + or - is used before the value, an increment or decrement of the current value is done.
 Set adjustment.
 Skip pages.
 Make a string smaller.
 Space vertically. lines can have any scaling factor, such as 3i or 8v.
 Table title. If refname is used, then the table number is saved with .SETR and can be retrieved with .GETST refname.

 [tlevel [tab [h1 [h2
 [h3 [h4 [h5]]]]]]]]]]
Table of contents. All texts can be redefined. new string variables Lifg, Litb, Liex, Liec, and Licon contain "Figure", "TABLE", "Exhibit", "Equation", and "CONTENTS". These can be redefined to other languages.
 Table end.
 Table header.
 Begin title of memorandum.
 Technical memorandum numbers used in .MT. Unlimited number of arguments may be given.
 Top of page user-defined macro. Note that header and footer is printed in a separate environment. Line length is preserved.
 Table start.
 User-defined table of contents exit.
 User-defined table of contents exit (no "CONTENTS").

VL [text-indent [mark-indent [1]]]
 VM [top [bottom]]
 WC [format]

Strings used in mgm:

EM
 HF
 HP
 Lf
 Lt
 Lx
 Le
 Rp
 Tm

Number variables used in mgm:

C1=2
 Cp=0
 D=0
 De=0
 Df=5
 Ds=1
 Ej=0
 Eq=0
 Fs=1
 H1 - H7
 Hb=2
 Hc=0
 Hi=1
 Hs=2
 Ht=0
 Hu=2
 Hy=1
 Lf=1, Lt=1, Lx=1, Le=0
 Li=6
 Ls=99
 N=0

Variable-item list start.
 Vertical margin.
 Footnote and display width control.

Em dash string.
 Font list for headings, usually "2 2 2 2 2 2". Nonnumeric font names may also be used.
 Point size list for headings. Usually "0 0 0 0 0 0", which is the same as "10 10 10 10 10 10".
 Contains "LIST OF FIGURES".
 Contains "LIST OF TABLES".
 Contains "LIST OF EXHIBITS".
 Contains "LIST OF EQUATIONS".
 Contains "REFERENCES".
 Contains \ (tm, trademark).

Contents level [0:7]; contents saved if heading level <=C1.
 Eject page between LIST OF XXXX if Cp == 0.
 Debug flag, values greater than 0 produce varying degree of debug. A value of 1 gives information about the progress of formatting.
 Eject after floating display is output [0:1].
 Floating keep output [0:5].
 Space before and after display if == 1 [0:1].
 Eject page.
 Equation label adjust 0=left, 1=right.
 Footnote spacing.
 Heading counters.
 Heading break level [0:7].
 Heading centering level [0:7].
 Heading temporary indent [0:2]. 0 is no indent, left margin. 1 is indent to right, like .P 1. 2 is indent to line up with text part of preceding heading.
 Heading space level [0:7]
 Heading numbering type 0 is multiple (1.1.1 ...). 1 is single.
 Unnumbered heading level.
 Hyphenation in body. 0 is no hyphenation. 1 is hyphenation 14 on.
 Enables (1) or disables (0) the printing of a list of figures, list of tables, list of exhibits, and list of equations.
 List indent, used by .AL.
 List space, if current list level is greater than Ls, then no spacing occurs around lists.
 Numbering style [0:5]:
 0 == (Default) Normal header for all pages.
 1 == Header replaces footer on first page; header is empty.
 2 == Page header is removed on the first page.

Np=0	3 == Section page numbering enabled.
Of=0	4 == Page header is removed on the first page.
P	5 == Section page and section figure numbering enabled. See also the number register <code>Sectf</code> and <code>Sectp</code> .
Pi=5	Numbered paragraphs. 0 is not numbered. 1 is numbered in first-level headings.
Ps=1	Format of figure, table, exhibit, and equation titles. 0 is ". ". 1 is "-".
Pt=0	Current page number, usually the same as % unless section-page numbering is enabled.
Si=5	Paragraph indent.
	Paragraph spacing.
	Paragraph type. 0 is left-justified. 1 is indented .P. 2 is indented .P except after .H, .DE, or .LE.
	Display indent.

groff_ms

groff_ms—groff ms macros.

SYNOPSIS

```
groff_mgs [ options... ] [ files... ]
```

DESCRIPTION

This manual page describes the GNU version of the `ms` macros, which is part of the `groff` document formatting system. The `groff ms` macros are intended to be compatible with the documented behavior of the 4.3 BSD UNIX `ms` macros, subject to the following limitations:

The internals of `groff ms` are not similar to the internals of UNIX `ms`, so documents that depend upon implementation details of UNIX `ms` might not work with `groff ms`.

There is no support for typewriter-like devices.

Berkeley localisms, in particular the `TM` and `CT` macros, are not implemented.

`groff ms` does not provide cut marks.

Multiple line spacing is not allowed. (Use a larger vertical spacing instead.)

`groff ms` does not work in compatibility mode (such as with the `-c` option).

The error-handling policy of `groff ms` is to detect and report errors, rather than silently ignore them.

The `groff ms` macros use many features of GNU `troff` and therefore cannot be used with any other `troff`.

Bell Labs localisms are not implemented in either the `BSD ms` macros or in the `groff ms` macros.

Some UNIX `ms` documentation says that the `CW` and `GW` number registers can be used to control the column width and gutter width. This is not the case. These number registers are not used in `groff ms`.

Macros that cause a reset set the indent. Macros that change the indent do not increment or decrement the indent, but rather set it absolutely. This can cause problems for documents that define additional macros of their own. The solution is to not use the `in request` but instead to use the `RS` and `RE` macros.

The number register `GS` is set to 1 by the `groff ms` macros but is not used by the UNIX `ms` macros. It is intended that documents that need to determine whether they are being formatted with UNIX `ms` or `groff ms` use this number register.

Footnotes are implemented so that they can safely be used within `keeps` and `displays`. Automatically numbered footnotes within floating `keeps` are not recommended. It is safe to have another `**` between a `**` and the corresponding `.FS`; it is required only that each `.FS` occur after the corresponding `**` and that the occurrences of `.FS` are in the same order as the corresponding occurrences of `**`.

The strings `*{` and `*}` can be used to begin and end a superscript.

Some UNIX `V10 ms` features are implemented. The `B`, `I`, and `BI` macros can have an optional third argument that is printed in the current font before the first argument. There is a macro `CW` like `B` that changes to a constant-width font.

The following strings can be redefined to adapt the `groff ms` macros to languages other than English:

<i>String</i>	<i>Default Value</i>
REFERENCES	References
ABSTRACT	ABSTRACT
TOC	Table of Contents
MONTH1	January
MONTH2	February
MONTH3	March
MONTH4	April
MONTH5	May
MONTH6	June
MONTH7	July
MONTH8	August
MONTH9	September
MONTH10	October
MONTH11	November
MONTH12	December

The font family is reset from the string `FAM`; at initialization if this string is undefined, it is set to the current font family. The point size, vertical spacing, and inter-paragraph spacing for footnotes are taken from the number registers `FPS`, `FVS`, and `FPD`; at initialization, these are set to $\lfloor n(PS-2) \rfloor$, $\lfloor n[FPS]+2 \rfloor$, and $\lfloor n(PD/2) \rfloor$; however, if any of these registers was defined before initialization, it is not set. The hyphenation flags (as set by the `.hy request`) are set from the `HY` register; if this was not defined at initialization, it is set to 14.

Right-aligned displays are available with `.DS R` and `.RD`.

The following conventions are used for names of macros, strings, and number registers. External names available to documents that use the `groff ms` macros contain only uppercase letters and digits. Internally, the macros are divided into

modules. Names used only within one module are of the form `module*name`. Names used outside the module in which they are defined are of the form `module@name`. Names associated with a particular environment are of the form `environment:name`; these are used only within the `par` module, and `name` does not have a module prefix. Constructed names used to implement arrays are of the form `array!index`. Thus, the `groff` macros reserve the following names:

Names containing *

Names containing @

Names containing :

Names containing only uppercase letters and digits

Groff Version 1.09, 9 January 1994

hier

`hier`—Description of the filesystem hierarchy.

DESCRIPTION

A typical Linux system has, among others, the following directories:

<code>/</code>	This is the root directory. This is where the whole tree starts.
<code>/bin</code>	This directory contains executable programs that are needed in single-user mode and to bring the system up or repair it.
<code>/boot</code>	Contains static files for the boot loader. This directory only holds the files that are needed during the boot process. The map installer and configuration files should go to <code>/sbin</code> and <code>/etc</code> .
<code>/dev</code>	Special or device files that refer to physical devices. See <code>mknod(1)</code> .
<code>/dos</code>	If both MS-DOS and Linux are run on one computer, this is a typical place to mount a DOS filesystem.
<code>/etc</code>	Contains configuration files that are local to the machine. Some larger software packages, such as X11, can have their own subdirectories below <code>/etc</code> . Site-wide configuration files may be placed here or in <code>/usr/etc</code> . Nevertheless, programs should always look for these files in <code>/etc</code> and you may have links for these files to <code>/usr/etc</code> .
<code>/etc/skel</code>	When a new user account is created, files from this directory are usually copied into the user's home directory.
<code>/etc/X11</code>	Configuration files for the X11 window system.
<code>/home</code>	On machines with home directories for users, these are usually beneath this directory, directly or not. The structure of this directory depends on local administration decisions.
<code>/lib</code>	This directory should hold those shared libraries that are necessary to boot the system and to run the commands in the root filesystem.
<code>/mnt</code>	This is a mount point for temporarily mounted filesystems.
<code>/proc</code>	This is a mount point for the <code>proc</code> filesystem, which provides information about running processes and the kernel. This pseudo-filesystem is described in more detail in <code>proc(5)</code> .

<code>/sbin</code>	Like <code>/bin</code> , this directory holds commands needed to boot the system but usually not executed by normal users.
<code>/tmp</code>	This directory contains temporary files that may be deleted with no notice, such as by a regular job or at system startup.
<code>/usr</code>	This directory is usually mounted from a separate partition. It should hold only sharable, read-only data so that it can be mounted by various machines running Linux.
<code>/usr/X11R6</code>	The X window system, version 11, release 6.
<code>/usr/X11R6/bin</code>	Binaries that belong to the X window system; often, there is a symbolic link from the more traditional <code>/usr/bin/X11</code> to here.
<code>/usr/X11R6/lib</code>	Data files associated with the X window system.
<code>/usr/X11R6/lib/X11</code>	These contain miscellaneous files needed to run X; Often, there is a symbolic link from <code>/usr/lib/X11</code> to this directory.
<code>/usr/X11R6/include/X11</code>	Contains include files needed for compiling programs using the X11 window system. Often, there is a symbolic link from <code>/usr/include/X11</code> to this directory.
<code>/usr/bin</code>	This is the primary directory for executable programs. Most programs executed by normal users that are not needed for booting or for repairing the system and that are not installed locally should be placed in this directory.
<code>/usr/bin/X11</code>	This is the traditional place to look for X11 executables; on Linux, it usually is a symbolic link to <code>/usr/X11R6/bin</code> .
<code>/usr/dict</code>	This directory holds files containing word lists for spell-checkers.
<code>/usr/etc</code>	Site-wide configuration files to be shared between several machines may be stored in this directory. However, commands should always reference those files using the <code>/etc</code> directory. Links from files in <code>/etc</code> should point to the appropriate files in <code>/usr/etc</code> .
<code>/usr/include</code>	Include files for the C compiler.
<code>/usr/include/X11</code>	Include files for the C compiler and the X window system. This is usually a symbolic link to <code>/usr/X11R6/include/X11</code> .
<code>/usr/include/asm</code>	Include files that declare some assembler functions. This should be a symbolic link to <code>/usr/src/linux/include/asm</code> .
<code>/usr/include/linux</code>	This contains information that may change from system release to system release and should be a symbolic link to <code>/usr/src/linux/include/linux</code> to get at operating-system-specific information.
<code>/usr/include/g++</code>	Include files to use with the GNU C++ compiler.
<code>/usr/lib</code>	Object libraries, including dynamic libraries, plus some executables that usually are not invoked directly. More complicated programs may have whole subdirectories there.
<code>/usr/lib/X11</code>	The usual place for data files associated with X programs and configuration files for the X system itself. On Linux, it usually is a symbolic link to <code>/usr/X11R6/lib/X11</code> .
<code>/usr/lib/gcc-lib</code>	Contains executables and include files for the GNU C compiler, <code>gcc(1)</code> .
<code>/usr/lib/groff</code>	Files for the GNU <code>groff</code> document formatting system.
<code>/usr/lib/uucp</code>	Files for <code>uucp(1)</code> .
<code>/usr/lib/zoneinfo</code>	Files for time zone information.
<code>/usr/local</code>	This is where programs that are local to the site typically go.
<code>/usr/local/bin</code>	Binaries for programs local to the site go there.
<code>/usr/local/doc</code>	Local documentation.
<code>/usr/local/etc</code>	Configuration files associated with locally installed programs go there.
<code>/usr/local/lib</code>	Files associated with locally installed programs go there.
<code>/usr/local/info</code>	Info pages associated with locally installed programs go there.
<code>/usr/local/man</code>	Man pages associated with locally installed programs go there.
<code>/usr/local/sbin</code>	Locally installed programs for system administration.

<code>/usr/local/src</code>	Source code for locally installed software.
<code>/usr/man</code>	Man pages go in there into their subdirectories.
<code>/usr/man/cat[1-9]</code>	These directories contain preformatted manual pages according to their man page section.
<code>/usr/man/local e/man[1-9]</code>	These directories contain manual pages that are in source code form. Systems that use a unique language and code set for all manual pages may omit the <code>local e</code> substring.
<code>/usr/sbin</code>	This directory contains program binaries for system administration that are not essential for the boot process, for mounting <code>/usr</code> , or for system repair.
<code>/usr/src</code>	Source files for different parts of the system.
<code>/usr/src/linux</code>	This contains the sources for the kernel of the operating system itself.
<code>/usr/tmp</code>	An alternative place to store temporary files; This should be a link to <code>/var/tmp</code> .
<code>/var</code>	This directory contains files that may change in size, such as spool and log files.
<code>/var/adm</code>	This directory is superseded by <code>/var/log</code> and should be a symbolic link to <code>/var/log</code> .
<code>/var/lock</code>	Lock files are placed in this directory. The naming convention for device lock files is <code>LCK..device</code> where <code>device</code> is the device's name in the filesystem. The format used is that of HDU UUCP lock files—that is, lock files contain a PID as a 10-byte ASCII decimal number, followed by a newline character.
<code>/var/log</code>	Miscellaneous log files.
<code>/var/preserve</code>	This is where <code>vi(1)</code> saves edit sessions so they can be restored later.
<code>/var/run</code>	Runtime variable files, such as files holding process identifiers (PIDs) and logged user information (<code>utmp</code>). Files in this directory are usually cleared when the system boots.
<code>/var/spool</code>	Spoiled (or queued) files for various programs.
<code>/var/spool/at</code>	Spoiled jobs for <code>at(1)</code> .
<code>/var/spool/cron</code>	Spoiled jobs for <code>cron(1)</code> .
<code>/var/spool/lpd</code>	Spoiled files for printing.
<code>/var/spool/mail</code>	Users' mailboxes.
<code>/var/spool/smail</code>	Spoiled files for the <code>smail(1)</code> mail delivery program.
<code>/var/spool/news</code>	Spool directory for the news subsystem.
<code>/var/spool/uucp</code>	Spoiled files for <code>uucp(1)</code> .
<code>/var/tmp</code>	Like <code>/tmp</code> , this directory holds temporary files stored for an unspecified duration.

CONFORMS TO

The Linux filesystem standard, release 1.2.

BUGS

This list is not exhaustive; different systems may be configured differently.

hostname

`hostname`—Hostname resolution description.

DESCRIPTION

Hostnames are domains. A domain is a hierarchical, dot-separated list of subdomains. For example, the machine `monet` in the `Berkeley` subdomain of the `EDU` subdomain of the Internet Domain Name System is represented as `monet.Berkeley.EDU` (with no trailing dot).

Hostnames are often used with network client and server programs, which must generally translate the name to an address for use. (This task is usually performed by the library routine `gethostbyname(3)`.) The default method for resolving hostnames by the Internet name resolver is to follow RFC 1535's security recommendations. Actions can be taken by the administrator to override these recommendations and to have the resolver behave the same as earlier, non-RFC 1535 resolvers.

The default method (using RFC 1535 guidelines) follows.

If the name consists of a single component (that is, contains no dot) and if the environment variable `HOSTALIASES` is set to the name of a file, that file is searched for a string matching the input hostname. The file should consist of lines made up of two strings separated by whitespace, the first of which is the hostname alias and the second of which is the complete hostname to be substituted for that alias. If a case-insensitive match is found between the hostname to be resolved and the first field of a line in the file, the substituted name is looked up with no further processing.

If there is at least one dot in the name, then the name is first tried as is. The number of dots to cause this action is configurable by setting the threshold using the `ndots` option in `/etc/resolv.conf` (default is 1). If the name ends with a dot, the trailing dot is removed, and the remaining name is looked up (regardless of the setting of the `ndots` option) and no further processing is done.

If the input name does not end with a trailing dot, it is looked up by searching through a list of domains until a match is found. If neither the `search` option in the `/etc/resolv.conf` file or the `LOCALDOMAIN` environment variable is used, then the search list of domains contains only the full domain specified by the `domain` option (in `/etc/resolv.conf`) or the domain used in the local hostname (see `hostname(1)` and `resolver(5)`). For example, if the `domain` option is set to `CS.Berkeley.EDU`, then only `CS.Berkeley.EDU` is in the search list and is the only domain appended to the partial hostname. For example, a setting of `lithium` makes `lithium.CS.Berkeley.EDU` the only name to be tried using the search list.

If the `search` option is used in `/etc/resolv.conf` or the environment variable, `LOCALDOMAIN` is set by the user, then the search list includes what is set by these methods. For example, if the `search` option contained `CS.Berkeley.EDU CChem.Berkeley.EDU Berkeley.EDU`, then the partial hostname (such as `lithium`) is tried with each domain name appended (in the same order specified). The resulting hostnames that are tried include

```
lithium.CS.Berkeley.EDU
lithium.CChem.Berkeley.EDU
lithium.Berkeley.EDU
```

The environment variable `LOCALDOMAIN` overrides the `search` and `domain` options, and if both `search` and `domain` options are present in the resolver configuration file, then only the last one listed is used (see `resolver(5)`).

If the name was not previously tried "as is" (that is, it fell below the `ndots` threshold or did not contain a dot), then the name as originally provided is attempted.

iso_8859_1

`iso_8859_1`—The ISO 8859-1 character set encoded in octal, decimal, and hexadecimal.

DESCRIPTION

The ISO 8859 standard includes several 8-bit extensions to the ASCII character set (also known as ISO 646-IRV). Especially important is ISO 8859-1, the Latin Alphabet No. 1, which has become widely implemented and may already be seen as the

de facto standard ASCII replacement. ISO 8859-1 supports the following languages: Afrikaans, Basque, Catalan, Danish, Dutch, English, Faeroes, Finnish, French, Galician, German, Icelandic, Irish, Italian, Norwegian, Portuguese, Scottish, Spanish, and Swedish. Note that the ISO 8859-1 characters are also the first 256 characters of ISO 10646 (Unicode).

ISO 8859 ALPHABETS

The full set of ISO 8859 alphabets includes

ISO 8859-1	West European languages (Latin-1)
ISO 8859-2	East European languages (Latin-2)
ISO 8859-3	Southeast European and miscellaneous languages (Latin-3)
ISO 8859-4	Scandinavian/Baltic languages (Latin-4)
ISO 8859-5	Latin/Cyrillic
ISO 8859-6	Latin/Arabic
ISO 8859-7	Latin/Greek
ISO 8859-8	Latin/Hebrew
ISO 8859-9	Latin-1 modification for Turkish (Latin-5)
ISO 8859-10	Lappish/Nordic/Eskimo languages (Latin-6)

ISO 8859-1 CHARACTERS

The following table displays the characters in ISO 8859 Latin-1, which are printable and unlisted in the `ascii(7)` manual page.

<i>Oct</i>	<i>Dec</i>	<i>Hex</i>	<i>Char</i>	<i>Description</i>
240	160	A0		No-break space

locale

Locale—Description of multi-language support.

SYNOPSIS

```
#include <locale.h>
```

DESCRIPTION

A locale is a set of language and cultural rules. These cover aspects such as language for messages, different character sets, lexicographic conventions, and so on. A program needs to be able to determine its locale and act accordingly to be portable to different cultures.

The header `<locale.h>` declares data types, functions and macros that are useful in this task.

The functions it declares are `setlocale()` to set the current locale and `localeconv()` to get information about number formatting.

There are different categories for local information a program might need; they are declared as macros. Using them as the first argument to the `setlocale()` function, it is possible to set one of these to the desired locale:

<code>LC_COLLATE</code>	This is used to change the behavior of the functions <code>strcoll()</code> and <code>strxfrm()</code> , which are used to compare strings in the local alphabet. For example, the German sharp s is sorted as “ss.”
<code>LC_TYPE</code>	This changes the behavior of the character handling and classification functions, such as <code>isupper()</code> and <code>toupper()</code> and the multi-byte character functions such as <code>mblen()</code> or <code>wctomb()</code> .
<code>LC_MONETARY</code>	Changes the behavior of the information returned by <code>localeconv()</code> , which describes the way numbers are usually printed, with details such as decimal point versus decimal comma.
<code>LC_MESSAGES</code>	Changes the language messages are displayed in.
<code>LC_TIME</code>	Changes the behavior of the <code>strftime()</code> function to display the current time in a locally acceptable form; for example, most of Europe uses a 24-hour clock versus the U.S. 12-hour clock.
<code>LC_ALL</code>	All of the above.

If the second argument to `setlocale()` is empty string for the default locale, it is determined using the following steps:

1. If there is a non-null environment variable `LC_ALL`, the value of `LC_ALL` is used.
2. If an environment variable with the same name as one of the preceding categories exists and is non-null, its value is used for that category.
3. If there is a non-null environment variable `LANG`, the value of `LANG` is used.

Values about local numeric formatting are made available in a `struct lconv` returned by the `localeconv()` function, which has the following declaration:

```
struct lconv
{
    /* Numeric (non-monetary) information. */
    char *decimal_point; /* Decimal point character. */
    char *thousands_sep; /* Thousands separator. */
    /* Each element is the number of digits in each group;
    elements with higher indices are farther left.
    An element with value CHAR_MAX means that no further grouping is done.
    An element with value 0 means that the previous element is used for all
    groups farther left. */
    char *grouping;
    /* Monetary information. */
};
```

```

/* First three chars are a currency symbol from ISO 4217.
Fourth char is the separator. Fifth char is ' '. */
char *int_curr_symbol;
char *currency_symbol; /* Local currency symbol. */
char *mon_decimal_point; /* Decimal point character. */
char *mon_thousands_sep; /* Thousands separator. */
char *mon_grouping; /* Like 'grouping' element (above). */

Linux, 24 April 1993

mailaddr

mailaddr—Mail addressing description.

DESCRIPTION

Mail addresses are based on the ARPANET protocol listed at the end of this manual page. These addresses are in the general format

```
user@domain
```

A domain is a hierarchical dot separated list of subdomains. For example, the address

```
eric@monet.berkeley.edu
```

is usually interpreted from right to left. The message should go to the ARPA name tables (which do not correspond exactly to the physical ARPANET) and then to the Berkeley gateway, after which it should go to the local host monet. When the message reaches monet, it is delivered to the user eric.

Unlike some other forms of addressing, this does not imply any routing. Thus, although this address is specified as an ARPA address, it might travel by an alternate route if that were more convenient or efficient. For example, at Berkeley, the associated message would probably go directly to monet over the Ethernet rather than go via the Berkeley ARPANET gateway.

ABBREVIATION

Under certain circumstances, it might not be necessary to type the entire domain name. In general, anything following the first dot may be omitted if it is the same as the domain from which you are sending the message. For example, a user on calder.berkeley.edu could send to eric@monet without adding the berkeley.edu because it is the same on both sending and receiving hosts.

Certain other abbreviations may be permitted as special cases. For example, at Berkeley, ARPANET hosts may be referenced without adding the berkeley.edu as long as their names do not conflict with a local host name.

COMPATIBILITY

Certain old address formats are converted to the new format to provide compatibility with the previous mail system. In particular,

user@host.ARPA

is allowed and

host:user

is converted to

user@host

to be consistent with the rcp(1) command.

Also, the syntax

host!user

is converted to

user@host.UUCP

This is usually converted back to the host!user form before being sent on for compatibility with older UUCP hosts.

The current implementation is not able to route messages automatically through the UUCP network. Until that time, you must explicitly tell the mail system which hosts to send your message through to get to your final destination.

CASE DISTINCTIONS

Domain names (anything after the @ sign) may be given in any mixture of uppercase and lowercase with the exception of UUCP hostnames. Most hosts accept any combination of case in usernames, with the notable exception of MULTICS sites.

ROUTE-ADDRS

Under some circumstances, it might be necessary to route a message through several hosts to get it to the final destination. Usually, this routing is done automatically, but sometimes it is desirable to route the message manually. Addresses that show these relays are termed "route-addr." These use the syntax

<@hosta,@hostb:user@hostc>

This specifies that the message should be sent to hosta, from there to hostb, and finally to hostc. This path is forced even if there is a more efficient path to hostc.

Route-addr occur frequently on return addresses because these are generally augmented by the software at each host. It is generally possible to ignore all but the user@domain part of the address to determine the actual sender.

POSTMASTER

Every site is required to have a user or user alias designated “postmaster” to which problems with the mail system may be addressed.

OTHER NETWORKS

Some other networks can be reached by giving the name of the network as the last component of the domain. This is not a standard feature and might not be supported at all sites. For example, messages to CSNET or BITNET sites can often be sent to `user@host.CSNET` or `user@host.BITNET`.

BUGS

The RFC 822 group syntax (`group:user1,user2,user3;`) is not supported except in the special case of `group:;` because of a conflict with old berknet-style addresses.

Route-Address syntax is grotty.

UUCP- and ARPANET-style addresses do not coexist politely.

man

`man`—Macros to format man pages.

SYNOPSIS

```
groff -Tascii -man file ...
groff -Tps -man file ...
man [section] title
```

DESCRIPTION

This manual page explains the `groff tmac.an` macro package. This macro package should be used by developers when writing or porting man pages for Linux. It is fairly compatible with other versions of this macro package, so porting man pages should not be a major problem (exceptions include the NET-2 BSD release, which uses a totally different macro package).

Note that NET-2 BSD man pages can be used with `groff` simply by specifying the `-mdoc` option instead of the `-man` option. Using the `-mandoc` option is, however, recommended because this automatically detects which macro package is in use.

PREAMBLE

The first command in a man page should be

```
.TH title section date source manual ,
```

`title`

The title of the man page (such as `MAN`).

`section`

The section number the man page should be placed in (such as 7).

`date`

The date of the last revision; remember to change this every time a change is made to the man page because this is the most general way of doing version control.

`source`

The source of the command.

For binaries, use something such as GNU, NET-2, SLS Distribution, MCC Distribution.

For system calls, use the version of the kernel that you are currently looking at:

Linux 0.99.11.

For library calls, use the source of the function: GNU, BSD 4.3, Linux DLL 4.4.1.

The title of the manual (such as *Linux Programmer's Manual*).

manual

The manual sections are traditionally defined as follows:

1 Commands	Those commands that can be executed by the user from within a shell.
2 System calls	Those functions that must be performed by the kernel.
3 Library calls	Most of the <code>libc</code> functions, such as <code>sort(3)</code> .
4 Special files	Files found in <code>/dev</code> .
5 File formats and conventions	The format for <code>/etc/passwd</code> and other human-readable files.
6 Games	
7 Macro packages and conventions	A description of the standard file system layout, this man page, and other things.
8 System management commands	Commands such as <code>mount(8)</code> , which only root can execute.
9 Kernel routines	This is a non-standard manual section and is included because the source code to the Linux kernel is freely available under the GNU Public License and many people are working on changes to the kernel.

FONTS

Although there are many arbitrary conventions for man pages in the UNIX world, the existence of several hundred Linux-specific man pages defines the standards:

For functions, the arguments are always specified using italics, even in the SYNOPSIS section, where the rest of the function is specified in bold:

```
int myfunction(int argc, char **argv);
```

Filenames are always in italics (such as `/usr/include/stdio.h`), except in the SYNOPSIS section, where included files are in bold (such as `#include <stdio.h>`).

Special macros, which are usually in uppercase, are in bold (such as `MAXINT`).

When enumerating a list of error codes, the codes are in bold (this list usually uses the `.TP` macro).

Any reference to another man page (or to the subject of the current man page) is in bold. If the manual section number is given, it is given in roman, without any spaces (such as `man(7)`).

The commands to select the typeface are given below:

<code>.B</code>	Bold
<code>.BI</code>	Bold alternating with italics
<code>.BR</code>	Bold alternating with Roman
<code>.I</code>	Italics
<code>.IB</code>	Italics alternating with bold
<code>.IR</code>	Italics alternating with Roman
<code>.RB</code>	Roman alternating with bold
<code>.RI</code>	Roman alternating with italics
<code>.SB</code>	Small alternating with bold
<code>.SM</code>	Small

Traditionally, each command can have up to six arguments, but the GNU version seems to remove this limitation. Arguments are delimited by spaces. Double quotes can be used to specify an argument that contains spaces. All the arguments will be printed next to each other without intervening spaces, so that the `.BR` command can be used to specify a word in bold followed by a mark of punctuation in Roman.

SECTIONS

Sections are started with `.SH` followed by the heading name. If the name contains spaces and appears on the same line as `.SH`, then place the heading in double quotes. Traditional headings include `NAME`, `SYNOPSIS`, `DESCRIPTION`, `OPTIONS`, `FILES`, `SEE ALSO`, `DIAGNOSTICS`, `BUGS`, and `AUTHOR`. The only required heading is `NAME`, which should be followed on the next line by a one line description of the program:

```
.SH NAME
chess \- the game of chess
```

It is extremely important that this format is followed and that there is a backslash before the single dash that follows the command name. This syntax is used by the `makewhatis(8)` program to create a database of short command descriptions for the `whatis(1)` and `apropos(1)` commands.

OTHER MACROS

Other macros include the following:

<code>.DT</code>	Default tabs.
<code>.HP</code>	Begin hanging indent.
<code>.IP</code>	Begin paragraph with hanging tag. This is the same as <code>.TP</code> , except the tag is given on the same line, not on the following line.
<code>.LP</code>	Same as <code>.PP</code> .
<code>.PD</code>	Set interparagraph distance to argument.
<code>.PP</code>	Begin a new paragraph.
<code>.RE</code>	End relative indent (indented paragraph).
<code>.RS</code>	Start relative indent (indented paragraph).
<code>.SS</code>	Subheading (like <code>.SH</code> but used for a subsection).
<code>.TP</code>	Begin paragraph with hanging tag. The tag is given on the next line. This command is similar to <code>.IP</code> .

FILES

```
/usr/local/lib/groff/tmac/tmac.an
/usr/man/whatis
```

Linux, 25 July 1993

signal

`signal`—List of available signals.

DESCRIPTION

Linux supports the signals listed in this section. Several signal numbers are architecture dependent. First are the signals described in `POSIX.1`:

`abort(3)` `alarm(1)` Next various other signals.

(Here, `-` denotes that a signal is absent; there, where three values are given, the first one is usually valid for alpha and sparc, the middle one for i386 and ppc, the last one for mips. Signal 29 is `SIGINFO/SIGPWR` on an alpha but `SIGLOST` on a sparc.)

The letters in the Action column have the following meanings:

A	Default action is to terminate the process.
B	Default action is to ignore the signal.
C	Default action is to dump core.
D	Default action is to stop the process.
E	Signal cannot be caught.
F	Signal cannot be ignored.
G	Not a POSIX.1 conformant signal.

CONFORMING TO
POSIX.1

BUGS

SIGIO and SIGLST have the same value. The latter is commented out in the kernel source, but the build process of some software still thinks that Signal 29 is SIGLST.

suffixes

suffixes—List of file suffixes.

DESCRIPTION

It is customary to indicate the contents of a file with the file suffix, which consists of a period followed by one or more letters. Many standard utilities, such as compilers, use this to recognize the type of file they are dealing with. The `make(1)` utility is driven by rules based on file suffixes.

Following is a list of suffixes that are likely to be found on a Linux system:

<i>Suffix</i>	<i>File Type</i>
.v	Files for RCS (Revision Control System)
-	Backup file
.C	C++ source code
.F	FORTRAN source with <code>cpp(1)</code> directives
.S	Assembler source with <code>cpp(1)</code> directives
.Z	File compressed using <code>compress(1)</code>
.[0-9]+pk	TeX font files
.[1-9]	Manual page for the corresponding section
.[1-9][a-z]	Manual page for section plus subsection
.a	Static object code library
.afm	PostScript font metrics
.arc	ARC archive
.arj	ARJ archive
.asc	PGP ASCII-armored data

continues

<i>Suffix</i>	<i>File Type</i>
.awk	AWK language program
.bak	Backup file
.bm	Bitmap source
.c	C source
.cat	Message catalog files
.cc	C++ source
.cf	Configuration file
.conf	Configuration file
.config	Configuration file
.cweb	Donald Knuth's WEB for C
.dat	Data file
.def	Modula-2 source for definition modules
.def	Other definition files
.diff	ASCII File differences
.doc	Documentation file
.dvi	TeX device independent output
.el	EMACS lisp source
.elc	Compiled EMACS lisp
.eps	Encapsulated PostScript
.f	FORTRAN source
.fas	Precompiled common lisp
.fi	FORTRAN include files
.gif	Graphics Interchange Format
.gsf	Ghostscript fonts
.gz	File compressed using <code>gzip(1)</code>
.h	C or C++ header files
.hlp	Help file
.htm	HTML file imported without renaming from a brain-damaged OS
.html	HTML document used with the World Wide Web
.i	C source after preprocessing
.idx	Reference or datum-index file for hypertext or database system
.icon	Bitmap source
.image	Bitmap source
.in	Configuration template, especially for GNU <code>autoconf</code>
.info	Files for the EMACS info browser
.java	A Java source file
.jpg	JPEG compressed picture format
.l	<code>lex(1)</code> or <code>flex(1)</code> files
.lib	Common lisp library
.ln	Files for use with <code>lint(1)</code>
.lsp	Common lisp source
.m4	<code>m4(1)</code> source
.mac	Macro files for various programs

<i>Suffix</i>	<i>File Type</i>
.man	Manual page (usually source rather than formatted)
.me	nroff source using the me macro package
.mf	Metafont (font generator for TeX) source
.mm	Sources for groff(1) in mm format
.mod	Modula-2 source for implementation modules
.o	Object file
.old	Old or backup file
.orig	Backup (original) version of a file from patch(1)
.out	Output file, often an executable program (a.out)
.p	Pascal source
.patch	File differences from patch(1)
.pcf	X11 font files
.pfa	PostScript font definition files, ASCII format
.pfb	PostScript font definition files, binary format
.pgp	PGP binary data
.pid	File to store daemon PID (such as crond.pid)
.png	Portable Network Graphics file
.pl	Perl script
.pr	Bitmap source
.ps	PostScript file
.r	RATFOR source (obsolete)
.rej	Patches that patch(1) couldn't apply
.rules	Rules for something
.s	Assembler source
.sa	Stub libraries for a.out shared libraries
.sc	sc(1) spreadsheet commands
.sh	sh(1) scripts
.shar	Archive created by the shar(1) utility
.so	DLL dynamic library
.sql	SQL schema or query program
.sty	LaTeX style files
.sym	Modula-2 compiled definition modules
.tar	Archive created by the tar(1) utility
.tar.Z	tar archive compressed with compress(1)
.tar.gz	tar archive compressed with gzip(1)
.taz	tar archive compressed with compress(1)
.tex	TeX or LaTeX source
.texi	Equivalent to .texinfo
.texinfo	TeXinfo documentation source
.tfm	TeX font metrics
.tgz	tar archive compressed with gzip(1)
.tmpl	Template files

continues

<i>Suffix</i>	<i>File Type</i>
.txt	Text file
.uue	Binary file encoded with <code>uuencode(1)</code>
.web	Donald Knuth's WEB
.y	<code>yacc(1)</code> or <code>bison(1)</code> (parser generator) files
.z	File compressed using <code>pack(1)</code> (or an old <code>gzip(1)</code>)
.zoo	ZOO archive
~	EMACS or patch backup file
rc	Startup (run control) file, such as <code>.newsrc</code>

CONFORMS TO

General UNIX conventions.

tr2tex

`tr2tex`—Convert a document from `troff` to LaTeX

SYNOPSIS

```
tr2tex [ -m ] filename
```

DESCRIPTION

`tr2tex` converts a document typeset in `troff` to a LaTeX format. It is intended to do the first pass of the conversion. The user should then finish up the rest of the conversion and customize the converted manuscript to his or her liking. It can also serve as a tutor for those who want to convert from `troff` to LaTeX.

Most of the converted document will be in LaTeX, but some of it may be in plain TeX. It will also use some macros in `troffms.sty` or `troffman.sty`, which are included in the package and must be available to the document when processed with LaTeX.

If there is more than one input file, they will all be converted into one LaTeX document.

`tr2tex` understands most of the `-ms` and `-man` macros and `eqn` preprocessor symbols. It also understands several plain `troff` commands. Few `tbl` preprocessor commands are understood to help convert very simple tables.

When converting manuals, use the `-m` flag.

If a `troff` command cannot be converted, the line that contain that command will be commented out.

Note that if you have `eqn` symbols, you must have the inline mathematics delimiter defined by `delim` in the file you are converting. If it is defined in another setup file, that setup file must be concatenated with the file to be converted; otherwise, `tr2tex` regards the inline math as ordinary text.

BUGS

Many of these bugs are harmless. Most of them cause local errors that can be fixed in the converted manuscript.

- Some macros and macro arguments are not recognized.
- Commands that are not separated from their argument by a space are not properly parsed (such as `.sp3i`).
- When some operators (notably `over`, `sub`, and `sup`) are renamed (via `define`) and then they are encountered in the text, `tr2tex` treats them as ordinary macros and does not apply their rules.
- `rpile`, `lpile`, and `cpile` are treated the same as `cpile`.
- `rcol` and `lcol` are treated the same as `ccol`.
- Math-mode `size`, `gsize`, `fat`, and `gfont` are ignored.
- `lineup` and `mark` are ignored. The rules are so different.
- Some `troff` commands are translated to commands that require delimiters that have to be explicitly put. Because they are sometimes not put in `troff`, they can create problems. Example: `.nf` is not closed by `.fi`.
- When local motions are converted to `nraise` or `nlower`, an `nhbox` is needed, which must be put manually after the conversion.
- `a sub i sub j` is converted to `a_i_j`, which TeX parses as `a_i{}_j` with a complaint that it is vague. `a sub {i sub j}` is parsed correctly and converted to `a_{i_j}`.
- Line spacing is not changed within a paragraph in TeX (which is a bad practice anyway). TeX uses the last line spacing in effect in that paragraph.

TO DO

Access registers via the `.nr` command.

Unicode

Unicode—The unified 16-bit super character set.

DESCRIPTION

The international standard ISO 10646 defines the Universal Character Set (UCS). UCS contains all the characters of all other character-set standards. It also guarantees round-trip compatibility; conversion tables can be built such that no information is lost when a string is converted from any other encoding to UCS and back.

UCS contains the characters required to represent almost all known languages. This includes apart from the many languages that use extensions of the Latin script also the following scripts and languages: Greek, Cyrillic, Hebrew, Arabic, Armenian, Gregorian, Japanese, Chinese, Hiragana, Katakana, Korean, Hangul, Devangari, Bengali, Gurmukhi, Gujarati, Oriya, Tamil, Telugu, Kannada, Malayam, Thai, Lao, Bopomofo, and a number of others. Work is going on to include further scripts such as Tibetan, Khmer, Runic, Ethiopian, Hieroglyphics, various Indo-European languages, and many others. For most of these latter scripts, it was not yet clear how they can be encoded best when the standard was published in 1993. In addition to the characters required by these scripts, also a large number of graphical, typographical, mathematical, and scientific symbols such as those provided by TeX, PostScript, MS-DOS, Macintosh, Videotext, OCR, and many word processing systems have been included, as well as special codes that guarantee round-trip compatibility to all other existing character-set standards.

The UCS standard (ISO 10646) describes a 31-bit character-set architecture; however, today only the first 65534 code positions (0x0000 to 0xffff), which are called the Basic Multilingual Plane (BMP), have been assigned characters, and it is expected that only very exotic characters (such as Hieroglyphics) for special scientific purposes will ever get a place outside this 16-bit BMP.

The UCS characters 0x0000 to 0x007f are identical to those of the classic US-ASCII character set and the characters in the range 0x0080 to 0x00ff are identical to those in the ISO 8859-1 Latin-1 character set.

COMBINING CHARACTERS

Some code points in UCS have been assigned to combining characters. These are similar to the non-spacing accent keys on a typewriter. A combining character just adds an accent to the previous character. The most important accented characters have codes of their own in UCS; however, the combining character mechanism allows you to add accents and other diacritical marks to any character. The combining characters always follow the character that they modify. For example, the German character Umlaut-A (“Latin capital letter A with diaeresis”) can either be represented by the precomposed UCS code 0x00c4 or alternately as the combination of a normal “Latin capital letter A” followed by a “combining diaeresis”: 0x0041 0x0308.

IMPLEMENTATION LEVELS

As not all systems are expected to support advanced mechanisms such as combining characters, ISO 10646 specifies the following three implementation levels of UCS:

- | | |
|---------|--|
| Level 1 | Combining characters and Hangul Jamo characters (a special, more complicated encoding of the Korean script, where Hangul syllables are coded as two or three subcharacters) are not supported. |
| Level 2 | Like level 1, except in some scripts, some combining characters are now allowed (such as Hebrew, Arabic, Devangari, Bengali, Gurmukhi, Gujarati, Oriya, Tamil, Telugo, Kannada, Malayalam, Thai, and Lao). |
| Level 3 | All UCS characters are supported. |

The Unicode 1.1 standard published by the Unicode Consortium contains exactly the UCS Basic Multilingual Plane at implementation Level 3, as described in ISO 10646. Unicode 1.1 also adds some semantical definitions for some characters to the definitions of ISO 10646.

UNICODE UNDER LINUX

Under Linux, only the BMP at implementation Level 1 should be used at the moment to keep the implementation complexity of combining characters low. The higher implementation levels are more suitable for special word processing formats but not as a generic system character set. The C type `wchar_t` is on Linux an unsigned 16-bit integer type and its values are interpreted as UCS Level 1 BMP codes.

The locale setting specifies whether the system character encoding is UTF-8 or ISO 8859-1, for example. Library functions such as `wctomb`, `mbtowc`, or `wprintf` can be used to transform the internal `wchar_t` characters and strings into the system character encoding and back.

PRIVATE AREA

In the BMP, the range 0xe000 to 0xf8ff will never be assigned any characters by the standard and is reserved for private usage. For the Linux community, this private area is subdivided further into the range 0xe000 to 0xefff, which can be used individually by any end user and the Linux zone in the range 0xf000 to 0xf8ff where extensions are coordinated among all Linux users. The registry of the characters assigned to the Linux zone is currently maintained by H. Peter Anvin (Peter.Anvin@linux.org), Yggdrasil Computing, Inc. It contains some DEC VT100 graphics characters missing in Unicode, gives direct access to the characters in the console font buffer, and contains the characters used by a few advanced scripts such as Klingon.

LITERATURE

Information technology—Universal Multiple-Octet Coded Character Set (UCS). Part 1: Architecture and Basic Multilingual Plane. International Standard ISO 10646-1, International Organization for Standardization, Geneva, 1993.

This is the official specification of UCS. Pretty official, pretty thick, and pretty expensive. For ordering information, check www.iso.ch.

The Unicode Standard—Worldwide Character Encoding Version 1.0. The Unicode Consortium, Addison-Wesley, Reading, MA, 1991.

There is already Unicode 1.1.4 available. The changes to the 1.0 book are available from [ftp.unicode.org](ftp://ftp.unicode.org). Unicode 2.0 will be published again as a book in 1996.

S. Harbison, G. Steele. C, *A Reference Manual*. Fourth edition, Prentice Hall, Englewood Cliffs, 1995, ISBN 0-13-326224-3.

A good reference book about the C programming language. The fourth edition now covers also the 1994 Amendment 1 to the ISO C standard (ISO/IEC 9899:1990), which adds a large number of new C library functions for handling wide character sets.

BUGS

At the time when this man page was written, the Linux `libc` support for UCS was far from complete.

UTF - 8

UTF-8—An ASCII-compatible multibyte Unicode encoding.

DESCRIPTION

The Unicode character set occupies a 16-bit code space. The most obvious Unicode encoding (known as UCS-2) consists of a sequence of 16-bit words. Such strings can contain as parts of many 16-bit characters bytes such as `\0` or `/`, which have a special meaning in filenames and other C library function parameters. In addition, the majority of UNIX tools expects ASCII files and can't read 16-bit words as characters without major modifications. For these reasons, UCS-2 is not a suitable external encoding of Unicode in filenames, text files, environment variables, and so on. The ISO 10646 Universal Character Set (UCS), a superset of Unicode, occupies even a 31-bit code space, and the obvious UCS-4 encoding for it (a sequence of 32-bit words) has the same problems.

The UTF-8 encoding of Unicode and UCS does not have these problems and is the way to go for using the Unicode character set under UNIX-style operating systems.

PROPERTIES

The UTF-8 encoding has the following nice properties:

UCS characters `0x00000000` to `0x0000007f` (the classical U.S. ASCII characters) are encoded simply as bytes `0x00` to `0x7f` (ASCII compatibility). This means that files and strings that contain only 7-bit ASCII characters have the same encoding under both ASCII and UTF-8.

All UCS characters greater than `0x7f` are encoded as a multibyte sequence consisting only of bytes in the range `0x80` to `0xfd`, so no ASCII byte can appear as part of another character and there are no problems with `\0` or `/`.

The lexicographic sorting order of UCS-4 strings is preserved.

All possible 2^{31} UCS codes can be encoded using UTF-8.

The bytes 0xfe and 0xff are never used in the UTF-8 encoding.

The first byte of a multibyte sequence that represents a single non-ASCII UCS character is always in the range 0xc0 to 0xfd and indicates how long this multibyte sequence is. All further bytes in a multibyte sequence are in the range 0x80 to 0xbf. This allows easy resynchronization and makes the encoding stateless and robust against missing bytes.

UTF-8–encoded UCS characters may be up to six bytes long; however, Unicode characters can only be up to three bytes long. Because Linux uses only the 16-bit Unicode subset of UCS, under Linux, UTF-8 multibyte sequences can only be one, two, or three bytes long.

ENCODING

The following byte sequences are used to represent a character. The sequence to be used depends on the UCS code number of the character:

```
0x00000000 - 0x0000007F: 0xxxxxxx
0x00000080 - 0x000007FF: 110xxxxx 10xxxxxx
0x00000800 - 0x0000FFFF: 1110xxxx 10xxxxxx 10xxxxxx
0x00010000 - 0x001FFFFF: 11110xxx 10xxxxxx 10xxxxxx 10xxxxxx
0x00200000 - 0x03FFFFFF: 111110xx 10xxxxxx 10xxxxxx 10xxxxxx 10xxxxxx
0x04000000 - 0x7FFFFFFF: 1111110x 10xxxxxx 10xxxxxx 10xxxxxx 10xxxxxx
10xxxxxx
```

The xxx-bit positions are filled with the bits of the character code number in binary representation. Only the shortest possible multibyte sequence that can represent the code number of the character can be used.

EXAMPLES

The Unicode character 0xa9 = 1010 1001 (the copyright sign) is encoded in UTF-8 as

```
11000010 10101001 = 0xc2 0xa9
```

and character 0x2260 = 0010 0010 0110 0000 (the “not equal” symbol) is encoded as

```
11100010 10001001 10100000 = 0xe2 0x89 0xa0
```

STANDARDS

ISO 10646, Unicode 1.1, XPG4, Plan 9.

**Administration
and Privileged
Commands**

intro

intro—Introduction to administration and privileged commands.

DESCRIPTION

This chapter describes commands that either can be or are only used by the superuser, such as daemons and machine or hardware-related commands.

AUTHORS

Linux, 24 July 1993

adduser, addgroup

adduser, addgroup—Add a user or group to the system.

SYNOPSIS

```
adduser [--system [--home directory] [--group]] [--quiet]
  [--force-badname] [--help] [--version] [--debug] username
adduser [--quiet] [--force-badname] [--help] [--version]
  [--debug] username group
adduser [--group] [--quiet] [--force-badname] [--help]
  [--version] [--debug] group
```

DESCRIPTION

adduser and addgroup add users and groups to the system according to information provided in the configuration file `/etc/adduser.conf`. adduser and addgroup automatically determine the UID or GID and place the entity in the password or group file as appropriate.

If necessary, adduser creates a home directory for the new user, copies “skeletal” user files to it from `/etc/skel`, and allows the system administrator to set an initial password and finger information for the user.

Because it needs to be able to write to such files as `/etc/passwd`, adduser can only be run as root.

Generally, there are two types of users and groups on a system: those users that log into the system and those “non-user” accounts and groups that exist for various system tasks and projects. Henceforth, user will refer to the login type and system user or group will refer to the type used for system maintenance and projects.

By default, each user in Debian GNU/Linux is given a corresponding group with the same name and ID, allowing people easily to give access to their home directories to others. This option can be turned off in the configuration file, in which case each user is, by default, added to a group called users.

Under Debian GNU/Linux, IDs less than or equal to 100 are allocated by the base system maintainer for various purposes. IDs from 101 to the value specified in the configuration file (1000, by default) are used for system users and groups. IDs greater than 1000 are reserved for users and their corresponding groups.

When invoked with a single name, adduser creates a user with that name. When given two names, adduser assumes that the first name represents an existing user and that the second name represents an existing group. In this case, the user is added to the group.

OPTIONS

<code>--system</code>	Create a system user. This user will be assigned the shell <code>/bin/false</code> and have an asterisk in the password field. Unless otherwise specified, the user will be placed in the group <code>nogroup</code> . Skeletal configuration files will not be copied into the user's home directory.
<code>--home directory</code>	When used with <code>--system</code> , this uses <code>directory</code> as the user's home directory, rather than the default specified in the configuration file. If the directory does not exist, it is created.
<code>--group</code>	When combined with <code>--system</code> , a group with the same name and ID as the system user is created. If not combined with <code>--system</code> , a group with the given name is created. This is the default action if the program is invoked as <code>addgroup</code> .
<code>--quiet</code>	Suppress progress messages.
<code>--force-badname</code>	By default, user and group names are required to consist of a lowercase letter followed by one or more lowercase letters or numbers. This option forces <code>adduser</code> or <code>addgroup</code> to be more lenient.
<code>--help</code>	Display brief instructions.
<code>--version</code>	Display version and copyright information.
<code>--debug</code>	Display a large quantity of debugging information.

Debian GNU/Linux version 1.94

agetty

agetty—Alternative Linux getty.

SYNOPSIS

```
agetty [-ihL] [-l login_program] [-m] [-t timeout] port baud_rate,... [term]
agetty [-ihL] [-l login_program] [-m] [-t timeout] baud_rate,... port [term]
```

DESCRIPTION

agetty opens a tty port, prompts for a login name, and invokes the `/bin/login` command. It is usually invoked by `init(8)`.

agetty has several non-standard features that are useful for hard-wired and for dial-in lines:

- Adapts the tty settings to parity bits and to erase, kill, end-of-line, and uppercase characters when it reads a login name. The program can handle 7-bit characters with even, odd, none, or space parity and 8-bit characters with no parity. The following special characters are recognized: @ and Control+U (kill); #, Del and Backspace (erase); carriage return and line feed (end of line).

- Optionally deduces the baud rate from the `CONNECT` messages produced by Hayes-compatible modems.

- Optionally does not hang up when it is given an already opened line (useful for call-back applications).

- Optionally does not display the contents of the `/etc/issue` file (System V only).

Optionally invokes a non-standard login program instead of `/bin/login`.

Optionally turns on hardware flow control.

Optionally forces the line to be local with no need for carrier detect.

This program does not use the `/etc/gettydefs` (System V) or `/etc/gettytab` (SunOS 4) files.

ARGUMENTS

<code>port</code>	A path name relative to the <code>/dev</code> directory. If a <code>-</code> is specified, <code>agetty</code> assumes that its standard input is already connected to a <code>tty</code> port and that a connection to a remote user has already been established. Under System V, a <code>-port</code> argument should be preceded by a <code>-</code> .
<code>baud rate,...</code>	A comma-separated list of one or more baud rates. Each time <code>agetty</code> receives a break character, it advances through the list, which is treated as if it were circular. Baud rates should be specified in descending order, so that the null character (<code>Ctrl+@</code>) can also be used for baud rate switching.
<code>term</code>	The value to be used for the <code>TERM</code> environment variable. This overrides whatever <code>init(8)</code> may have set and is inherited by <code>login</code> and the shell.

OPTIONS

<code>-h</code>	Enable hardware (RTS/CTS) flow control. It is left up to the application to disable software (XON/XOFF) flow protocol where appropriate.
<code>-i</code>	Do not display the contents of <code>/etc/issue</code> before writing the login prompt. Terminals or communications hardware might become confused when receiving lots of text at the wrong baud rate; dial-up scripts might fail if the login prompt is preceded by too much text.
<code>-l login_program</code>	Invoke the specified login program instead of <code>/bin/login</code> . This allows the use of a non-standard login program (for example, one that asks for a dial-up password or that uses a different password file).
<code>-m</code>	Try to extract the baud rate the connect status message produced by some Hayes-compatible modems. These status messages are of the form: " <code><junk><speed><junk></code> ". <code>agetty</code> assumes that the modem emits its status message at the same speed as specified with (the first) baud rate value on the command line. Because the <code>-m</code> feature might fail on heavily loaded systems, you still should enable break processing by enumerating all expected baud rates on the command line.
<code>-t timeout</code>	Terminate if no username could be read within <code>timeout</code> seconds. This option should probably not be used with hard-wired lines.
<code>-L</code>	Force the line to be a local line with no need for carrier detect. This can be useful when you have a locally attached terminal where the serial line does not set the carrier detect signal.

EXAMPLES

This section shows sample entries for the `/etc/inittab` file.

For a hard-wired line:

```
tty1:con80x60:/sbin/agetty 9600 tty1
```

For a dial-in line with a 9600/2400/1200 baud modem:

```
ttyS1:dumb:/sbin/agetty -mt60 ttyS1 9600,2400,1200
```

These examples assume you use the `simpleinit(8)` `init` program for Linux. If you use a SysV-like `init` (does `/etc/inittab` mention “respawn?”), refer to the appropriate manual page.

ISSUE ESCAPES

The `/etc/issue` file might contain certain escape codes to display the system name, date and time, and so on. All escape codes consist of a backslash (`\`) immediately followed by one of the following letters:

<code>b</code>	Insert the baudrate of the current line.
<code>d</code>	Insert the current date.
<code>s</code>	Insert the system name, the name of the operating system.
<code>l</code>	Insert the name of the current <code>tty</code> line.
<code>m</code>	Insert the architecture identifier of the machine, such as <code>i486</code> .
<code>n</code>	Insert the nodename of the machine, also known as the hostname.
<code>o</code>	Insert the domain name of the machine.
<code>r</code>	Insert the release number of the OS, such as <code>1.1.9</code> .
<code>t</code>	Insert the current time.
<code>u</code>	Insert the number of current users logged in.
<code>U</code>	Insert the string <code>1 user</code> or <code>n users</code> where <code>n</code> is the number of current users logged in.
<code>v</code>	Insert the version of the OS, such as the build date and so on.

For example, on my system, the following `/etc/issue` file

```
This is \n.\o (\s\m\r) \t
```

displays as

```
This is thing01.orcan.dk (Linux i386 1.1.9) 18:29:30
```

FILES

- `/var/run/utmp`, the system status file
- `/etc/issue`, printed before the login prompt (System V only)
- `/dev/console`, problem reports (if `syslog(3)` is not used)
- `/etc/inittab` (Linux `simpleinit(8)` configuration file)

BUGS

The baud-rate detection feature (the `-m` option) requires that `agetty` be scheduled soon enough after completion of a dial-in call (within 30ms with modems that talk at 2400 baud). For robustness, always use the `-m` option in combination with a multiple baud rate command-line argument so that break processing is enabled.

The text in the `/etc/issue` file and the login prompt are always output with 7-bit characters and space parity.

The baud-rate detection feature (the `-m` option) requires that the modem emits its status message after raising the DCD line.

DIAGNOSTICS

Depending on how the program was configured, all diagnostics are written to the console device or reported via the `syslog(3)` facility. Error messages are produced if the port argument does not specify a terminal device, if there is no `utmp` entry for the current process (System V only), and so on.

archive

`archive`—Usenet article archiver.

SYNOPSIS

`archive [-a archive] [-f] [-i index] [-m] [-r] [input]`

DESCRIPTION

`archive` makes copies of files specified on its standard input. It is usually run either as a channel feed under `innd(8)` or by a script before `expire(8)` is run.

`archive` reads the named input file or standard input if no file is given. The input is taken as a set of lines. Blank lines and lines starting with a number sign (#) are ignored. All other lines should specify the name of a file to archive. If a filename is not an absolute pathname, it is taken to be relative to `/news/spool`.

Files are copied to a directory within the archive directory, `/news/spool/news.archive`. The default is to create a hierarchy that mimics the input files; intermediate directories are created as needed. For example, the input file `comp/sources/unix/2211` (article 2211 in the newsgroup `comp.sources.unix`) is copied to `/news/spool/news.archive/comp/sources/unix/2211`. If the `-f` flag is used, then all directory names are flattened out, replacing the slashes with periods. In this case, the file is copied to `/news/spool/news.archive/comp.sources.unix/2211`.

If the `-i` flag is used, then `archive` appends one line to the specified index file for each article that it copies. This line contains the destination name and the Message-ID and Subject headers.

For example, a typical `newsfeeds(5)` entry to archive most source newsgroups is as follows:

```
source-archive\
:!*,*sources*,!*wanted*,!*.*d\
:Tc,Wn\
:/archive -f -i \
/usr/spool/news/news.archive/INDEX
```

Files are copied by making a link. If that fails, a new file is created. If the `-m` flag is used, then the file is copied to the destination, and the input file is replaced with a symbolic link pointing to the new file. The `-m` flag is ignored.

By default, `archive` sets its standard error to `/var/log/news/errlog`. To suppress this redirection, use the `-r` flag.

If the input is exhausted, `archive` exits with a zero status. If an I/O error occurs, it tries to spool its input, copying it to a file. If there was no input filename, the standard input is copied to `/news/spool/out.going/archive` and the program exits. If an input filename was given, a temporary file named `input.bch` (if input is an absolute pathname) or `/news/spool/out.going/input.bch` (if the filename does not begin with a slash) is created. Once the input is copied, `archive` tries to rename this temporary file to be the name of the input file and then exits.

arp

arp—Manipulate the system ARP cache.

SYNOPSIS

```
arp [-v] [-t type] -a [hostname]
arp [-v] -d hostname ...
arp [-v] [-t type] -s hostname hw_addr
arp [-v] -f filename
```

DESCRIPTION

arp manipulates the kernel's ARP cache in various ways. The primary options are clearing an address mapping entry and manually setting up one. For debugging purposes, the arp program also allows a complete dump of the ARP cache.

OPTIONS

-v	Tell the user what is going on by being verbose.
-t type	When setting or reading the ARP cache, this optional parameter tells arp which class of entries it should check for. The default value of this parameter is ether (hardware code 0x01 for IEEE 802.3 10Mbps Ethernet). Other values might include network technologies such as ARCnet (arcnet), PRONet (pronet), and AX.25 (ax25).
-a [hostname]	Shows the entries of the specified hosts. If the hostname parameter is not used, all entries are displayed.
-d hostname	Remove the entries of the specified host. This can be used if the indicated host is brought down, for example.
-s hostname hw_addr	Manually create an ARP address mapping entry for host hostname with hardware address set to hw_addr. The format of the hardware address is dependent on the hardware class, but for most classes, you can assume that the usual presentation can be used. For the Ethernet class, this is six bytes in hexadecimal, separated by colons.
-f filename	Similar to the -s option, only this time the address info is taken from file filename. This can be used if ARP entries for a lot of hosts have to be set up. The name of the data file is often /etc/ethers, but this is not official. The format of the file is simple; it only contains ASCII text lines with a hostname and a hardware address separated by whitespace.

In all places where a hostname is expected, you can also enter an IP address in dotted-decimal notation.

FILES

/proc/net/arp
/etc/ethers

badblocks

`badblocks`—Search a device for bad blocks.

SYNOPSIS

```
badblocks [ -b block-size ] [ -o output_file ] [ -v ][-w ] device blocks-count
```

DESCRIPTION

`badblocks` is used to search for bad blocks on a device (usually a disk partition). `device` is the special file corresponding to the device (such as `/dev/hdXX`). `blocks-count` is the number of blocks on the device.

OPTIONS

<code>-b block-size</code>	Specify the size of blocks in bytes.
<code>-o output_file</code>	Write the list of bad blocks to the specified file. Without this option, <code>badblocks</code> displays the list on its standard output.
<code>-v</code>	Verbose mode.
<code>-w</code>	Use write-mode test. With this option, <code>badblocks</code> scans for bad blocks by writing some patterns (0xaa, 0x55, 0xff, and 0x00) on every block of the device, reading every block and comparing the contents.

WARNING

Never use the `-w` option on a device containing an existing filesystem. This option erases data!

AUTHOR

`badblocks` was written by Remy Card (`card@masi.ibp.fr`), the developer and maintainer of the `ext2 fs`.

BUGS

I had no chance to make real tests of this program because I use IDE drives, which remap bad blocks. I only made some tests on floppies.

AVAILABILITY

`badblocks` is available for anonymous FTP from `ftp.ibp.fr` and `tsx-11.mit.edu` in `/pub/linux/packages/ext2fs`.

Version 0.5b, November 1994

buffchan

`buffchan`—Buffered file-writing back end for InterNetNews.

SYNOPSIS

```
buffchan [ -b ][-c lines ][-C seconds ][-d directory ]
[-f fields ][-m map ][-p pidfile ][-l lines ][-L seconds ]
[-r ][-s file_format ][-u ]
```

DESCRIPTION

`buffchan` reads lines from standard input and copies certain fields in each line into files named by other fields within the line. `buffchan` is intended to be called by `innd(8)` as an exploder feed.

`buffchan` input is interpreted as a set of lines. Each line contains a fixed number of initial fields, followed by a variable number of filename fields. All fields in a line are separated by whitespace. The default number of initial fields is one; the `-f` flag may be used to specify a different number of fields. See `filechan(8)` for an example.

After the initial fields, each remaining field names a file to write. The `-s` flag may be used to specify a format string that maps the field to a filename. This is a `sprintf(3)` format string, which should have a single `%s` parameter that is given the field. The default value is `/news/spool/out.going/%s`. See the description of this flag in `filechan(8)`. The `-d` flag may be used to specify a directory the program should change to before starting. If this flag is used, then the default for the `-s` flag is changed to be a simple `%s`.

Once `buffchan` opens a file, it keeps it open. The input must therefore never specify more files than the number of available descriptors can keep open. If the `-b` flag is used, the program will allocate a buffer and attach it to the file using `setbuf(3)`. If the `-u` flag is used, the program will request unbuffered output.

If the `-l` flag is used with a number `n`, then `buffchan` will call `fflush(3)` after every `n` lines are written to a file. If the `-c` flag is used with a number `n`, then `buffchan` will close, and reopen, a file after every `n` lines are written to a file.

If the `-L` flag is used with a number `n`, then all files will be flushed every `n` seconds. Similarly, the `-c` flag may be used to specify that all files should be closed and reopened every `n` seconds.

By default, the program sets its standard error to `/var/log/news/errlog`. To suppress this redirection, use the `-r` flag.

If the `-p` flag is used, the program will write a line containing its process ID (in text) to the specified file.

`buffchan` can be invoked as an exploder feed (see `newsfeeds(5)`). As such, if a line starts with an exclamation point, it is treated as a command. There are three commands:

<code>flush</code>	The <code>flush</code> command closes and reopens all open files; <code>flush xxx</code> flushes only the specified site. These are analogous to the <code>ctlinnd(8)</code> <code>flush</code> command and can be achieved by doing a <code>send flush xxx</code> command. Applications can tell that the flush has completed by renaming the file before issuing the command; <code>buffchan</code> has completed the command when the original filename reappears. <code>buffchan</code> also changes the access permissions of the file from read-only for everyone to read-write for owner and group as it flushes or closes each output file. It changes the modes back to read-only if it reopens the same file.
<code>drop</code>	The <code>drop</code> command is similar to the <code>flush</code> command except that any files are not reopened. If given an argument, then the specified site is dropped; otherwise, all sites are dropped. (Note that the site will be restarted if the input stream mentions the site.) When a <code>ctlinnd</code> “drop site” command is sent, <code>innd</code> will automatically forward the command to <code>buffchan</code> if the site is a funnel that feeds into this exploder. To drop all sites, use the <code>ctlinnd send buffchan-site drop</code> command.
<code>readmap</code>	The map file (specified with the <code>-m</code> flag) is reloaded.

cfdisk

`cfdisk`—Curses-based disk partition table manipulator for Linux.

SYNOPSIS

```
cfdisk [ -avz ] [ -c cylinders ][-h heads ][-s sectors-per-track ][-P opt ]
[device ]
```

DESCRIPTION

`cfdisk` is a curses-based program for partitioning a hard disk drive. The device can be any one of the following:

```
/dev/hda [default]
/dev/hdb
/dev/sda
/dev/sdb
/dev/sdc
/dev/sdd
```

`cfdisk` first tries to read the geometry of the hard disk. If it fails, an error message is displayed and `cfdisk` exits. This should only happen when partitioning a SCSI drive on an adapter without a BIOS. To correct this problem, you can set the cylinders, heads, and sectors-per-track on the command line. Next, `cfdisk` tries to read the current partition table from the disk drive. If it is unable to figure out the partition table, an error is displayed and the program exits. This might also be caused by incorrect geometry information and can be overridden on the command line. Another way around this problem is with the `-z` option. This will ignore the partition table on the disk.

The main display is composed of four sections, from top to bottom: the header, the partitions, the command line, and a warning line. The header contains the program name and version number followed by the disk drive and its geometry. The partitions section always displays the current partition table. The command line is the place where commands and text are entered. The available commands are usually displayed in brackets. The warning line is usually empty except when there is important information to be displayed. The current partition is highlighted with reverse video (or an arrow if the `-a` option is given). All partition-specific commands apply to the current partition.

The format of the partition table in the partition's section is, from left to right: Name, Flags, Partition Type, Filesystem Type, and Size. The name is the partition device name. The flags can be `boot`, which designates a bootable partition or `NC`, which stands for "Not Compatible with DOS or OS/2." DOS, OS/2, and possibly other operating systems require the first sector of the first partition on the disk and all logical partitions to begin on the second head. This wastes the second through the last sector of the first track of the first head (the first sector is taken by the partition table itself). `cfdisk` allows you to recover these "lost" sectors with the `maximize` command (`m`). Note that `fdisk(8)` and some early versions of DOS create all partitions with the number of sectors already maximized. For more information, see the `maximize` command later in this chapter. The partition type can be `Primary` or `Logical`. For unallocated space on the drive, the partition type can also be `Pri/Log` or empty (if the space is unusable). The filesystem type section displays the name of the filesystem used on the partition, if known. If it is unknown, then `Unknown` and the hex value of the filesystem type are displayed. A special case occurs when there are sections of the disk drive that cannot be used (because all the primary partitions are used). When this is detected, the filesystem type is displayed as `Unusable`. The `size` field displays the size of the partition in megabytes (by default). It can also display the size in sectors and cylinders (see the `change units` command later in this chapter). If an asterisk (*) appears after the size, this means that the partition is not aligned on cylinder boundaries.

DOS 6.X WARNING

The DOS 6.X `FORMAT` command looks for some information in the first sector of the data area of the partition and treats this information as more reliable than the information in the partition table. DOS `FORMAT` expects DOS `FDISK` to clear the first 512 bytes of the data area of a partition whenever a size change occurs. DOS `FORMAT` looks at this extra information even if the `/U` flag is given; we consider this a bug in DOS `FORMAT` and DOS `FDISK`.

The bottom line is that if you use `cfdisk` or `fdisk` to change the size of a DOS partition table entry and then you must also use `dd` to zero the first 512 bytes of that partition before using DOS `FORMAT` to format the partition. For example, if you were using `cfdisk` to make a DOS partition table entry for `/dev/hda1`, then (after exiting `fdisk` or `cfdisk` and rebooting Linux so that the partition table information is valid), you use the command `dd if=/dev/zero of=/dev/hda1 bs=512 count=1` to zero the first 512 bytes of the partition.

Be extremely careful if you use the `dd` command because a small typo can make all of the data on your disk useless.

For best results, you should always use an OS-specific partition table program. For example, you should make DOS partitions with the DOS `FDISK` program and Linux partitions with the Linux `fdisk` or Linux `cfdisk` program.

COMMANDS

`cfdisk` commands can be entered by pressing the desired key (pressing Enter after the command is not necessary). Here is a list of the available commands:

- b** Toggle bootable flag of the current partition. This allows you to select which primary partition is bootable on the drive.
- d** Delete the current partition. This will convert the current partition into free space and merge it with any free space immediately surrounding the current partition. A partition already marked as free space or marked as unusable cannot be deleted.
- g** Change the disk geometry (cylinders, heads, or sectors-per-track). Warning: This option should only be used by people who know what they are doing. A command-line option is also available to change the disk geometry. While at the change disk geometry command line, you can choose to change cylinders (*d*), heads (*h*), and sectors per track (*s*). The default value will be printed at the prompt, which you can accept by simply pressing the Enter key or you can exit without changes by pressing the Esc key. If you want to change the default value, simply enter the desired value and press Enter. The altered disk parameter values do not take effect until you return to the main menu (by pressing Enter or Esc at the change disk geometry command line. If you change the geometry such that the disk appears larger, the extra sectors are added at the end of the disk as free space. If the disk appears smaller, the partitions that are beyond the new last sector are deleted and the last partition on the drive (or the free space at the end of the drive) is made to end at the new last sector.
- h** Print the help screen.
- m** Maximize disk usage of the current partition. This command will recover the the unused space between the partition table and the beginning of the partition, at the cost of making the partition incompatible with DOS, OS/2, and possibly other operating systems. This option will toggle between maximal disk usage and DOS, OS/2, and so on compatible disk usage. The default when creating a partition is to create DOS, OS/2, and so on compatible partitions.
- n** Create new partitions from free space. If the partition type is `Primary` or `Logical`, a partition of that type will be created, but if the partition type is `Pri/Log`, you will be prompted for the type you want to create. Be aware that there are only four slots available for primary partitions and because there can be only one extended partition that contains all of the logical drives, all of the logical drives must be contiguous (with no intervening primary partition). `cfdisk` next prompts you for the size of the partition you want to create. The default size, equal to the entire free space of the current partition, is displayed in megabytes. You can either press the Enter key to accept the default size or enter a different size at the prompt. `cfdisk` accepts size entries in megabytes (*M*) (default), kilobytes (*K*), cylinders (*d*), and sectors (*s*) when you enter the number immediately followed by *M*, *K*, *C*, or *S*. If the partition fills the free space available, the partition is created and you are returned to the main command line. Otherwise, the partition can be created at the beginning or the end of the free space, and `cfdisk` will ask you to choose where to place the partition. After the partition is created, `cfdisk` automatically adjusts the other partition's partition types if all of the primary partitions are used.
- p** Print the partition table to the screen or to a file. There are several different formats for the partition that you can choose from:
- r** Raw data format (exactly what would be written to disk).
- s** Partition table in sector order format.
- t** Partition table in raw format. The raw data format will print the sectors that would be written to disk if a `write` command is selected. First, the primary partition table is printed, followed by the partition tables associated with each logical partition. The data is printed in hex byte-by-byte with 16 bytes per line. The partition table in sector order format will print the partition table ordered by sector number. The fields, from left to right, are the number of the partition, the partition type, the first sector, the last sector, the offset from the first sector of the partition to the start of the data, the

length of the partition, the filesystem type (with the hex value in parentheses), and the flags (with the hex value in parentheses). In addition to the primary and logical partitions, free and unusable space is printed and the extended partition is printed before the first logical partition.

If a partition does not start or end on a cylinder boundary or if the partition length is not divisible by the cylinder size, an asterisk (*) is printed after the non-aligned sector number/count. This usually indicates that a partition was created by an operating system that either does not align partitions to cylinder boundaries or that used different disk geometry information. If you know the disk geometry of the other operating system, you can enter the geometry information with the change geometry command (g).

For the first partition on the disk and for all logical partitions, if the offset from the beginning of the partition is not equal to the number of sectors per track (that is, the data does not start on the first head), a number sign (#) is printed after the offset. For the remaining partitions, if the offset is not zero, a number sign is printed after the offset. This corresponds to the `nc` flag in the partitions section of the main display.

The partition table in raw format will print the partition table ordered by partition number. It will leave out all free and unusable space. The fields, from left to right, are the number of the partition, the flags (in hex), the starting head, sector, and cylinder, the filesystem ID (in hex), the ending head, sector, and cylinder, the starting sector in the partition, and the number of sectors in the partition. The information in this table can be directly translated to the raw data format. The partition table entries only have 10 bits available to represent the starting and ending cylinders. Thus, when the absolute starting (ending) sector number is on a cylinder greater than 1023, the maximal values for starting (ending) head, sector, and cylinder are printed. This is the method used by OS/2, and it fixes the problems associated with OS/2's `fdisk` rewriting the partition table when it is not in this format. Because Linux and OS/2 use absolute sector counts, the values in the starting and ending head, sector, and cylinder are not used.

q	Quit program. This will exit the program without writing any data to disk.
t	Change the filesystem type. By default, new partitions are created as Linux partitions, but because <code>fdisk</code> can create partitions for other operating systems, changing the partition type allows you to enter the hex value of the filesystem you desire. A list of the known filesystem types is displayed. You can type the filesystem type at the prompt or accept the default filesystem type (Linux).
u	Change units of the partition size display. It will rotate through megabytes, sectors, and cylinders.
w	Write partition table to disk (you must enter an uppercase <code>w</code>). Because this might destroy data on the disk, you must either confirm or deny the write by entering <code>yes</code> or <code>no</code> . If you enter <code>yes</code> , <code>fdisk</code> will write the partition table to disk and tell the kernel to re-read the partition table from the disk. The re-reading of the partition table works in most cases, but I have seen it fail. Don't panic. It will be correct after you reboot the system. In all cases, I still recommend rebooting the system just to be safe.
Up arrow, Down arrow	Move cursor to the previous or next partition. If there are more partitions than can be displayed on a screen, you can display the next (previous) set of partitions by moving down (up) at the last (first) partition displayed on the screen.
Ctrl+L	Redraws the screen. In case something goes wrong and you cannot read anything, you can refresh the screen from the main command line.
?	Print the help screen.

All the commands can be entered with either uppercase or lowercase letters (except for writes). When in a submenu or at a prompt to enter a filename, you can hit the `Esc` key to return to the main command line.

OPTIONS

-a	Use an arrow cursor instead of reverse video for highlighting the current partition.
-v	Print the version number and copyright.

- z Start with zeroed partition table. This option is useful when you want to repartition your entire disk. Note that this option does not zero the partition table on the disk; rather, it simply starts the program without reading the existing partition table.
 - c cylinders
 - h heads
 - s sectors-per-track
- Override the number of cylinders, heads, and sectors-per-track read from the BIOS. If your BIOS or adapter does not supply this information or if it supplies incorrect information, use these options to set the disk geometry values.
- P opt
- Prints the partition table in specified formats. `opt` can be one or more of `r`, `s`, or `t`. See the `print` command for more information on the print formats.

SEE ALSO

`fdisk(8)`

BUGS

The current version does not support multiple disks (future addition).

The BOGUS Linux Release, 3 June 1995

chat

chat—Automated conversational script with a modem.

SYNOPSIS

chat [options] script

DESCRIPTION

The `chat` program defines a conversational exchange between the computer and the modem. Its primary purpose is to establish the connection between the Point-to-Point protocol daemon (`pppd`) and the remote's `pppd` process.

OPTIONS

- f <chat file> Read the chat script from the chat file. The use of this option is mutually exclusive with the chat script parameters. The user must have read access to the file. Multiple lines are permitted in the file. Space or horizontal tab characters should be used to separate the strings.
- t <timeout> Set the time-out for the expected string to be received. If the string is not received within the time limit, then the reply string is not sent. An alternate reply may be sent or the script will fail if there is no alternate reply string. A failed script will cause the chat program to terminate with a nonzero error code.
- r <report file> Set the file for output of the report strings. If you use the keyword `REPORT`, the resulting strings are written to this file. If this option is not used and you still use `REPORT` keywords, the `stderr` file is used for the report strings.
- v Request that the chat script be executed in a verbose mode. The chat program will then log all text received from the modem and the output strings that it sends to the `SYSLOG`.

-v	Request that the chat script be executed in a <code>stderr</code> verbose mode. The chat program will then log all text received from the modem and the output strings that it sends to the <code>stderr</code> device. This device is usually the local console at the station running the chat or <code>pppd</code> program. This option does not work properly if the <code>stderr</code> is redirected to the <code>/dev/null</code> location because in that case <code>pppd</code> should run in the detached mode. In that case, use the <code>-v</code> option to record the session on the <code>SYSLOG</code> device.
script	If the script is not specified in a file with the <code>-f</code> option, then the script is included as parameters to the chat program.

CHAT SCRIPT

The chat script defines the communications.

A script consists of one or more “expect-send” pairs of strings, separated by spaces, with an optional “subexpect-sendsend” string pair, separated by a dash as in the following example:

```
ogin:-BREAK-ogin: ppp ssword: hello2u2
```

This line indicates that the chat program should expect the string `ogin:.` If it fails to receive a login prompt within the time interval allotted, it is to send a break sequence to the remote and then expect the string `ogin:.` If the first `ogin:.` is received, then the break sequence is not generated.

Once it receives the login prompt, the chat program will send the string `ppp` and then expect the prompt `ssword:.` When it receives the prompt for the password, it will send the password `hello2u2.`

A carriage return is usually sent following the reply string. It is not expected in the “expect” string unless it is specifically requested by using the `nr` character sequence.

The expect sequence should contain only what is needed to identify the string. Because it is usually stored on a disk file, it should not contain variable information. It is generally not acceptable to look for time strings, network identification strings, or other variable pieces of data such as an expect string.

To help correct for characters that may be corrupted during the initial sequence, look for the string `ogin:` rather than `login:.` It is possible that the leading `l` character might be received in error and you might never find the string even though it was sent by the system. For this reason, scripts look for `ogin:` rather than `login:` and `ssword:` rather than `password:.`

A very simple script might look like this:

```
ogin: ppp ssword: hello2u2
```

In other words, expect `...ogin:.`, send `ppp`, expect `...ssword:.`, send `hello2u2.`

In actual practice, simple scripts are rare. At the very least, you should include subexpect sequences in case the original string is not received. For example, consider the following script:

```
ogin:-ogin: ppp ssword: hello2u2
```

This is a better script than the simple one used earlier. This looks for the same `login:` prompt; however, if one was not received, a single return sequence is sent and then it will look for `login:` again. Should line noise obscure the first login prompt then sending the empty line will usually generate a login prompt again.

ABORT STRINGS

Many modems will report the status of the call as a string. These strings may be `CONNECTED` or `NO CARRIER` or `BUSY`. It is often desirable to terminate the script if the modem fails to connect to the remote. The difficulty is that a script does not know exactly which modem string it might receive. On one attempt, it might receive `BUSY`, but the next time, it might receive `NO CARRIER`.

These “abort” strings can be specified in the script using the `ABORT` sequence. It is written in the script as in the following example:

```
ABORT BUSY ABORT 'NO CARRIER' " ATZ OK ATDT5551212 CONNECT
```

This sequence will expect nothing and then send the string `ATZ`. The expected response to this is the string `OK`. When it receives `OK`, the string `ATDT5551212` dials the telephone. The expected string is `CONNECT`. If the string `CONNECT` is received, the remainder of the script is executed. However, if the modem finds a busy telephone, it sends the string `BUSY`. This causes the string to match the abort character sequence. The script then fails because it found a match to the abort string. If it received the string `NO CARRIER`, it aborts for the same reason. Either string may be received. Either string will terminate the chat script.

REPORT STRINGS

A report string is similar to the `ABORT` string. The difference is that the strings and all characters to the next control character such as a carriage return, are written to the report file.

The report strings may be used to isolate the transmission rate of the modem's connect string and return the value to the chat user. The analysis of the report string logic occurs in conjunction with the other string processing such as looking for the expect string. The use of the same string for a report and abort sequence is probably not very useful; however, it is possible.

The report strings do not change the completion code of the program.

These "report" strings may be specified in the script using the `REPORT` sequence. It is written in the script as in the following example:

```
REPORT CONNECT ABORT BUSY " ATDT5551212 CONNECT " ogin: account
```

This sequence expects nothing and then sends the string `ATDT5551212` to dial the telephone. The expected string is `CONNECT`. If the string `CONNECT` is received, the remainder of the script is executed. In addition, the program writes to the expect-file the string `CONNECT` plus any characters that follow it such as the connection rate.

TIME-OUT

The initial time-out value is 45 seconds. This may be changed using the `-t` parameter.

To change the time-out value for the next expect string, the following example may be used:

```
ATZ OK ATDT5551212 CONNECT TIMEOUT 10 ogin:-ogin: TIMEOUT 5 password:: hello2u2
```

This changes the time-out to 10 seconds when it expects the `login: prompt`. The time-out is then changed to 5 seconds when it looks for the password prompt.

The time-out, once changed, remains in effect until it is changed again.

SENDING EOT

The special reply string of `EOT` indicates that the chat program should send an `EOT` character to the remote. This is usually the End-of-file character sequence. A return character is not sent following the `EOT`. The `EOT` sequence may be embedded into the send string using the sequence `^D`.

GENERATING BREAK

The special reply string of `BREAK` causes a break condition to be sent. The break is a special signal on the transmitter. The normal processing on the receiver is to change the transmission rate. It may be used to cycle through the available transmission rates on the remote until you are able to receive a valid login prompt. The break sequence may be embedded into the send string using the `\K` sequence.

ESCAPE SEQUENCES

The expect and reply strings may contain escape sequences. All the sequences are legal in the reply string. Many are legal in the expect. Those that are not valid in the expect sequence are so indicated.

<code>''</code>	Expects or sends a null string. If you send a null string, it will still send the return character. This sequence may either be a pair of apostrophe or quote characters.
<code>\\b</code>	Represents a backspace character.

<code>\\c</code>	Suppresses the newline at the end of the reply string. This is the only method to send a string without a trailing return character. It must be at the end of the send string. For example, the sequence <code>hello\\c</code> will simply send the characters <code>h, e, l, l, o</code> . (Not valid in expect.)
<code>\\d</code>	Delay for one second. The program uses <code>sleep(1)</code> , which will delay to a maximum of one second. (Not valid in expect.)
<code>\\K</code>	Insert a <code>BREAK</code> . (Not valid in expect.)
<code>\\n</code>	Send a newline or linefeed character.
<code>\\N</code>	Send a null character. The same sequence may be represented by <code>\\0</code> . (Not valid in expect.)
<code>\\p</code>	Pause for a fraction of a second. The delay is one tenth of a second. (Not valid in expect.)
<code>\\q</code>	Suppress writing the string to the <code>SYSLOG</code> file. The string <code>?????</code> is written to the log in its place. (Not valid in expect.)
<code>\\r</code>	Send or expect a carriage return.
<code>\\s</code>	Represents a space character in the string. This may be used when it is not desirable to quote the strings that contains spaces. The sequence <code>HI TIM</code> and <code>HI\\sTIM</code> are the same.
<code>\\t</code>	Send or expect a tab character.
<code>\\\\</code>	Send or expect a backslash character.
<code>\\ddd</code>	Collapse the octal digits (<code>ddd</code>) into a single ASCII character and send that character. (Some characters are not valid in expect.)
<code>^c</code>	Substitute the sequence with the control character represented by <code>c</code> . For example, the character <code>DC1</code> (17) is shown as <code>^Q</code> . (Some characters are not valid in expect.)

TERMINATION CODES

The chat program will terminate with the following completion codes:

0	The normal termination of the program. This indicates that the script was executed without error to the normal conclusion.
1	One or more of the parameters are invalid or an expect string was too large for the internal buffers. This indicates that the program as not properly executed.
2	An error occurred during the execution of the program. This may be due to a read or write operation failing for some reason or chat receiving a signal such as <code>SIGINT</code> .
3	A time-out event occurred when there was an expect string without having a <code>-subsend</code> string. This may mean that you did not program the script correctly for the condition or that some unexpected event occurred and the expected string could not be found.
4	The first string marked as an <code>ABORT</code> condition occurred.
5	The second string marked as an <code>ABORT</code> condition occurred.
6	The third string marked as an <code>ABORT</code> condition occurred.
7	The fourth string marked as an <code>ABORT</code> condition occurred.
...	The other termination codes are also strings marked as an <code>ABORT</code> condition.

Using the termination code, it is possible to determine which event terminated the script. It is possible to decide if the string `BUSY` was received from the modem as opposed to `NO DIAL TONE`. Although the first event may be retried, the second will probably have little chance of succeeding during a retry.

SEE ALSO

Additional information about chat scripts may be found with UUCP documentation. The chat script was taken from the ideas proposed by the scripts used by the `uucico` program.

clock

`clock`—Manipulate the CMOS clock.

SYNOPSIS

```
/sbin/clock [ -u ] -r  
/sbin/clock [ -u ] -w  
/sbin/clock [ -u ] -s  
/sbin/clock [ -u ] -a
```

DESCRIPTION

`clock` manipulates the CMOS clock in various ways, allowing it to be read or written and allowing synchronization between the CMOS clock and the kernel's version of the system time.

OPTIONS

-u	Indicates that the CMOS clock is set to Universal Time.
-r	Read CMOS clock and print the result to <code>stdout</code> .
-w	Write the system time into the CMOS clock.
-s	Set the system time from the CMOS clock.
-a	Set the system time from the CMOS clock, adjusting the time to correct for systematic error and writing it back into the CMOS clock. This option uses the file <code>/etc/adjtime</code> to determine how the clock changes. It contains three numbers. The first number is the correction in seconds per day. (For example, if your clock runs 5 seconds fast each day, the first number should read <code>-5.0</code> .) The second number tells when clock was last used in seconds since 1/1/1970. The third number is the remaining part of a second that was leftover after the last adjustment.

The following instructions are from the source code:

1. Create a file `/etc/adjtime` containing as the first and only line `0.0 0 0.0`.
2. Run `clock -au` or `clock -a`, depending on whether your CMOS is in Universal or Local Time. This updates the second number.
3. Set your system time using the date command.
4. Update your CMOS time using `clock -wu` or `clock -w`.
5. Replace the first number in `/etc/adjtime` by your correction.
6. Put the command `clock -au` or `clock -a` in your `/etc/rc.local` or let `cron(8)` start it regularly.

FILES

`/etc/adjtime`
`/etc/rc.local`

comsat

comsat—Biff server

SYNOPSIS

comsat

DESCRIPTION

comsat is the server process that receives reports of incoming mail and notifies users if they requested this service. comsat receives messages on a datagram port associated with the biff service specification (see `services(5)` and `inetd(8)`). The one-line messages are of the form

```
user@mail | box-offset
```

If the user specified is logged in to the system and the associated terminal has the owner execute bit turned on (by a biff y), the offset is used as a seek offset into the appropriate mailbox file and the first 7 lines or 560 characters of the message are printed on the user's terminal. Lines that appear to be part of the message header other than the From, To, Date, or Subject lines are not included in the displayed message.

FILES

`/var/run/utmp` to find out who's logged on and on what terminals

SEE ALSO

`biff(1)`, `inetd(8)`

BUGS

The message header filtering is prone to error. The density of the information presented is near the theoretical minimum.

Users should be notified of mail that arrives on other machines than the one to which they are currently logged in.

The notification should appear in a separate window so it does not mess up the screen.

HISTORY

The command appeared in BSD 4.2.

BSD 4.2, 16 March 1991

crond

crond—cron daemon (Dillon's Cron).

SYNOPSIS

```
crond [-l#] [-d[#]] [-f] [-b] [-c directory]
```

OPTIONS

crond is a background daemon that parses individual crontab files and executes commands on behalf of the users in question.

-l log level	Set logging level; default is 8.
-d [debug] level	Set debugging level; default is 0. If no level is specified with the -d option, the default is 1. This option also sets the logging level to 0 and causes crond to run in the foreground.
-f	Run crond in the foreground.
-b	Run crond in the background (the default unless -d is specified).
-c directory	Specify directory containing crontab files.

DESCRIPTION

crond is responsible for scanning the crontab files and running their commands at the appropriate time. The crontab program communicates with crond through the cron.update file, which resides in the crontabs directory, usually /var/spool/cron/crontabs. This is accomplished by appending the filename of the modified or deleted crontab file to cron.update, which crond then picks up to resynchronize or remove its internal representation of the file.

crond has a number of built-in limitations to reduce the chance of it being ill-used. Potentially infinite loops during parsing are dealt with via a failsafe counter, and user crontabs are generally limited to 256 crontab entries. crontab lines may not be longer than 1024 characters, including the newline.

Whenever crond must run a job, it first creates a daemon-owned temporary file O_EXCL and O_APPEND to store any output, and then it fork()s and changes its user and group permissions to match that of the user the job is being run for. Then, it executes /bin/sh -c to run the job. The temporary file remains under the ownership of the daemon to prevent the user from tampering with it. Upon job completion, crond verifies the secureness of the mail file and, if it has been appended to, mails to the file to user. The sendmail program is run under the user's UID to prevent mail-related security holes. Unlike crontab, the crond program does not leave an open descriptor to the file for the duration of the job's execution because this might cause crond to run out of descriptors. When the crontab program allows a user to edit his crontab, it copies the crontab to a user-owned file before running the user's preferred editor. The suid crontab program keeps an open descriptor to the file, which it later uses to copy the file back, thereby ensuring the user has not tampered with the file type.

crond always synchronizes to the top of the minute, checking the current time against the list of possible jobs. The list is stored such that the scan goes very quickly, and crond can deal with several thousand entries without taking any noticeable amount of CPU.

ctlinnd

ctlinnd—Control the InterNetNews daemon.

SYNOPSIS

```
ctlinnd [ -h ][-s ][-t timeout ] command [ argument... ]
```

DESCRIPTION

ctlinnd sends a message to the control channel of innd(8), the InterNetNews server.

In the normal mode of behavior, the message is sent to the server, which then performs the requested action and sends back a reply with a text message and the exit code for ctlinnd. If the server successfully performed the command, ctlinnd will exit with a status of zero and print the reply on standard output. If the server could not perform the command (for example, it was told to remove a newsgroup that does not exist), it will direct ctlinnd to exit with a status of one. The shutdown, xabort, and xexec commands do not generate a reply; ctlinnd will always exit silently with a status of zero. If the -s flag is used, then no message will be printed if the command was successful.

The -t flag can be used to specify how long to wait for the reply from the server. The timeout value specifies the number of seconds to wait. A value of zero waits forever, and a value less than zero indicates that no reply is needed. When waiting for a reply, ctlinnd will try every two minutes to see if the server is still running, so it is unlikely that -t0 will hang. The default is -t0.

To see a command summary, use the -h flag. If a command is included when ctlinnd is invoked with the -h flag, then only the usage for that command will be given.

If a large number of groups are going to be created or deleted at once, it may be more efficient to pause or throttle the server and edit the active file directly.

The complete list of commands follows. Note that all commands have a fixed number of arguments. If a parameter can be an empty string, then it is necessary to specify it as two adjacent quotes ("").

addhistMessage-ID arr exp post paths	Add an entry to the history database. This directs the server to create a history line for Message-ID. The angle brackets are optional. arr, exp, and post specify when the article arrived, what its expiration date is, and when it was posted. All three values are a number indicating the number of seconds since the epoch. If the article does not have an Expires header, then exp should be zero. paths is the pathname within the newspool directory where the article is filed. If the article is cross-posted, then the names should be separated by whitespace and the paths argument should be inside double quotes. If the server is paused or throttled, this command causes it to briefly open the history database.
allow reason	Remote connections are allowed. The reason must be the same text given with an earlier reject command or an empty string.
begin site	Begin feeding site. This will cause the server to rescan the newsfeeds(5) file to find the specified site and set up a newsfeed for it. If the site already exists, a "drop" is done first. This command is forwarded; see below.
cancel <Message-ID>	Remove the article with the specified Message-ID from the local system. This does not generate a cancel message. The angle brackets are optional. If the server is paused or throttled, this command causes it to briefly open the history database.
changegroup group rest	The newsgroup group is changed so that its fourth field in the active file becomes the value specified by the rest parameter. This may be used to make an existing group moderated or unmoderated, for example.
checkfile	Check the syntax of the newsfeeds file, and display a message if any errors are found. The details of the errors are reported to syslog(3).

drop site	Flush and drop <code>site</code> from the server's list of active feeds. This command is forwarded; see below.
flush site	Flush the buffer for the specified <code>site</code> . The actions taken depend on the type of feed the site receives; see <code>newsfeeds(5)</code> . This is useful when the site is fed by a file and batching is going to start. If <code>site</code> is an empty string, then all sites are flushed and the active file and history databases are also written out. This command is forwarded; see below.
flushlogs	Close the log and error log files and rename them to have a <code>.old</code> extension. The history database and active file are also written out.
go reason	Reopen the history database and start accepting articles after a pause or throttle command. The <code>reason</code> must either be an empty string or match the text that was given in the earlier pause or throttle command. If a reject command was done, this will also do an allow command if the reason matches the text that was given in the reject. If a reserve command was done, this will also clear the reservation if the reason matches the text that was given in the reserve. Note that if only the history database has changed while the server is paused or throttled, it is not necessary to send it a reload command before sending it a go command. If the server throttled itself because it accumulated too many I/O errors, this command will reset the error count. If the server was not started with the <code>-ny</code> flag, then this command also does a readers command with <code>yes</code> as the flag and <code>reason</code> as the text.
hangup channel	Close the socket on the specified incoming <code>channel</code> . This is useful when an incoming connection appears to be hung.
help [command]	Print a command summary for all commands, or just <code>command</code> if specified.
mode	Print the server's operating mode as a multiline summary of the parameters and operating state.
name nnn	Print the name of channel number <code>nnn</code> or of all channels if it is an empty string.
newgroup group rest creator	Create the specified newsgroup. The <code>rest</code> parameter should be the fourth field as described in <code>active(5)</code> ; if it is not an equal sign, only the first letter is used. The <code>creator</code> should be the name of the person creating the group. If the newsgroup already exists, this is equivalent to the <code>changegroup</code> command. This is the only command that has defaults. The <code>creator</code> can be omitted and will default to the empty string, and the <code>rest</code> parameter can be omitted and will default to <code>y</code> . This command can be done while the server is paused or throttled; it will update its internal state when a go command is sent. This command updates the <code>active.times</code> (see <code>active(5)</code>) file.
param letter value	Change the command-line parameters of the server. The combination of defaults makes it possible to use the text of the Control header directly. <code>letter</code> is the <code>innd</code> command-line option to set, and <code>value</code> is the new value. For example, <code>i 5</code> directs the server to allow only five incoming connections. To enable or disable the action of the <code>-n</code> flag, use the letter <code>y</code> or <code>n</code> for the <code>value</code> .
pause reason	Pause the server so that no incoming articles are accepted. No existing connections are closed, but the history database is closed. This command should be used for short-term locks, such as when replacing the history files. If the server was not started with the <code>-ny</code> flag, then this command also does a readers command with <code>no</code> as the flag and <code>reason</code> as the text.
readers flag text	Allow or disallow newsreaders. If <code>flag</code> starts with the letter <code>n</code> , then newsreading is disallowed by causing the server to pass the text as the value of the <code>nnrpd(8) -r</code> flag. If <code>flag</code> starts with the letter <code>y</code> and <code>text</code> is either an empty

	string, or the same string that was used when newsreading was disallowed, then newsreading will be allowed.
reject reason	Remote connections (those that would not be handed off to nnrpd) are rejected, with <code>reason</code> given as the explanation.
reload what reason	The server updates its in-memory copies of various configuration files. <code>what</code> identifies what should be reloaded. If it is an empty string or the word <code>all</code> , then everything is reloaded; if it is the word <code>history</code> , then the history database is closed and opened; if it is the word <code>hosts.nntp</code> , then the <code>hosts.nntp(5)</code> file is reloaded; if it is the word <code>active</code> or <code>newsfeeds</code> , then both the active and newsfeeds files are reloaded; if it is the word <code>overview.fmt</code> , then the <code>overview.fmt(5)</code> file is reloaded. The <code>reason</code> is reported to <code>syslog</code> . There is no way to reload the data <code>inn.conf(5)</code> file; the server currently only uses the <code>pathhost</code> parameter, so this restriction should not be a problem.
renumber group	Scan the spool directory for the specified newsgroup and update the low-water mark in the active file. If <code>group</code> is an empty string, then all newsgroups are scanned.
reserve reason	The next pause or throttle command must use <code>reason</code> as its text. This reservation is cleared by giving an empty string for the <code>reason</code> . This command is used by programs such as <code>expire(8)</code> that want to avoid running into other instances of each other.
rmgroup group	Remove the specified newsgroup. This is done by editing the active file. The spool directory is not touched, and any articles in the group will be expired using the default expiration parameters. Unlike the <code>newsgroup</code> command, this command does not update the <code>active.times</code> file.
send feed text...	The specified <code>text</code> is sent as a control line to the exploder feed.
shutdown reason	The server is shut down, with the specified <code>reason</code> recorded in the log and sent to all open connections. It is a good idea to send a throttle command first.
signal sig site	Signal <code>sig</code> is sent to the specified <code>site</code> , which must be a channel or exploder feed. <code>sig</code> can be a numeric signal number or the word <code>hup</code> , <code>int</code> , or <code>term</code> ; case is not significant.
throttle reason	Input is throttled so that all existing connections are closed and new connections are rejected. The history database is closed. This should be used for long-term locks, such as when <code>expire</code> is being run. If the server was not started with the <code>-ny</code> flag, then this command also does a <code>readers</code> command with <code>no</code> as the flag and <code>reason</code> as the text.
trace item flag	Tracing is turned on or off for the specified <code>item</code> . <code>flag</code> should start with the letter <code>y</code> or <code>n</code> to turn tracing on or off. If <code>item</code> starts as a number, then tracing is set for the specified <code>innd</code> channel, which must be for an incoming NNTP feed. If it starts with the letter <code>I</code> , then general <code>innd</code> tracing is turned on or off. If it starts with the letter <code>n</code> , then future <code>nnrpd</code> 's will or will not have the <code>-t</code> flag enabled, as appropriate.
xabort reason	The server logs the specified <code>reason</code> and then invokes the <code>abort(3)</code> routine.
xexec path	The server gets ready to shut itself down, but instead of exiting, it executes the specified <code>path</code> with all of its original arguments. If <code>path</code> is <code>innd</code> , then <code>/news/bin/innd</code> is invoked; if it is <code>inndstart</code> , then <code>/news/bin/inndstart</code> is invoked; if it is an empty string, it will invoke the appropriate program depending on whether it was started with the <code>-p</code> flag; any other value is an error.

In addition to being acted upon within the server, certain commands can be forwarded to the appropriate child process. If the site receiving the command is an exploder (such as `buffchan(8)`) or it is a funnel that feeds into an exploder, then the command can be forwarded. In this case, the server will send a command line to the exploder that consists of the `ctlinn` command name. If the site funnels into an exploder that has an asterisk (*) in its `w` flag (see `newsfeed(5)`), then the site name is appended to the command; otherwise, no argument is appended.

BUGS

`ctlinn` uses the `inncomm(3)` library and is therefore limited to server replies no larger than 4KB.

ctrlaltdel

`ctrlaltdel`—Set the function of the Ctrl+Alt+Del combination.

SYNOPSIS

```
ctrlaltdel hard|soft
```

DESCRIPTION

Based on examination of the `linux/kernel/sys.c` code, it is clear that there are two supported functions that the Ctrl+Alt+Del sequence can perform: a hard reset, which immediately reboots the computer without calling `sync(2)` and without any other preparation, and a soft reset, which sends the `SIGINT` (interrupt) signal to the `init` process (this is always the process with PID 1). If this option is used, the `init(8)` program must support this feature. Because there are now several `init(8)` programs in the Linux community, consult the documentation for the version that you are currently using.

`ctrlaltdel` is usually used in the `/etc/rc.local` file.

FILES

`/etc/rc.local`

Linux 0.99, 25 October 1993

cvsgub

`cvsgub`—Send problem report (PR) about CVS to a central support site.

SYNOPSIS

```
cvsgub [ site ] [-f problem-report] [-t mail-address] [-P] [-L ]  
[ --request-id ] [-v ]
```

DESCRIPTION

`cvsbug` is a tool used to submit problem reports (PRs) to a central support site. In most cases, the correct site will be the default. This argument indicates the support site that is responsible for the category of problem involved. Some sites may use a local address as a default. Site values are defined by using the `aliases(5)`.

`cvsbug` invokes an editor on a problem report template (after trying to fill in some fields with reasonable default values). When you exit the editor, `cvsbug` sends the completed form to the Problem Report Management System (GNATS) at a central support site. At the support site, the PR is assigned a unique number and is stored in the GNATS database according to its category and submitter ID. GNATS automatically replies with an acknowledgment, citing the category and the PR number.

To ensure that a PR is handled promptly, it should contain your (unique) submitter ID and one of the available categories to identify the problem area. (Use `cvsbug -L` to see a list of categories.)

The `cvsbug` template at your site should already be customized with your submitter ID (running `install-sid submitter-id` to accomplish this is part of the installation procedures for `cvsbug`). If this hasn't been done, see your system administrator for your submitter ID, or request one from your support site by invoking `cvsbug --request-id`. If your site does not distinguish between different user sites, or if you are not affiliated with the support site, use `net` for this field.

The more precise your problem description and the more complete your information, the faster your support team can solve your problems.

OPTIONS

- `-f problem-report` Specify a file (`problem-report`) that already contains a complete problem report. `cvsbug` sends the contents of the file without invoking the editor. If the value for `problem-report` is `-`, then `cvsbug` reads from standard input.
- `-t mail-address` Change mail address at the support site for problem reports. The default `mail-address` is the address used for the default site. Use the site argument rather than this option in nearly all cases.
- `-P` Print the form specified by the environment variable `PR_FORM` on standard output. If `PR_FORM` is not set, print the standard blank PR template. No mail is sent.
- `-L` Print the list of available categories. No mail is sent.
- `--request-id` Sends mail to the default support site, or `site` if specified, with a request for your submitter ID. If you are not affiliated with `site`, use a submitter ID of `net`.
- `-v` Display the `cvsbug` version number.

Note: Use `cvsbug` to submit problem reports rather than mail them directly. Using both the template and `cvsbug` itself will help ensure all necessary information will reach the support site.

ENVIRONMENT

The environment variable `EDITOR` specifies the editor to invoke on the template. The default is `vi`.

If the environment variable `PR_FORM` is set, then its value is used as the filename of the template for your problem-report editing session. You can use this to start with a partially completed form (for example, a form with the identification fields already completed).

HOW TO FILL OUT A PROBLEM REPORT

Problem reports have to be in a particular form so that a program can easily manage them. Please remember the following guidelines:

- Describe only one problem with each problem report.

- For follow-up mail, use the same subject line as the one in the automatic acknowledgment. It consists of category, PR number, and the original synopsis line. This allows the support site to relate several mail messages to a particular PR and to record them automatically.

Please try to be as accurate as possible in the subject or synopsis line.

The subject and the synopsis line are not confidential. This is because open-bugs lists are compiled from them. Avoid putting confidential information there.

See the GNU Info file `cvsubug.info` or the document *Reporting Problems With cvsubug* for detailed information on reporting problems

HOW TO SUBMIT TEST CASES, CODE, AND SO ON

Submit small code samples with the PR. Contact the support site for instructions on submitting larger test cases and problematic source code.

FILES

`/tmp/p$$$` copy of PR used in editing session

`/tmp/pf$$$` copy of empty PR form, for testing purposes

`/tmp/pbad$$$` file for rejected PRs

EMACS USER INTERFACE

An EMACS user interface for `cvsubug` with completion of field values is part of the `cvsubug` distribution (invoked with `M-x cvsubug`). See the file `cvsubug.info` or the ASCII file `INSTALL` in the top-level directory of the distribution for configuration and installation information. The EMACS LISP template file is `cvsubug-e1.in` and is installed as `cvsubug.e1`.

INSTALLATION AND CONFIGURATION

See `cvsubug.info` or `INSTALL` for installation instructions.

SEE ALSO

Reporting Problems Using cvsubug (also installed as the GNU Info file `cvsubug.info`).

cvtbatch

`cvtbatch`—Convert Usenet batch file to INN format.

SYNOPSIS

`cvtbatch [-w items]`

DESCRIPTION

`cvtbatch` reads standard input as a series of lines, converts each line, and writes it to standard output. It is used to convert simple batchfiles that contain just the article name to INN batchfiles that contain additional information about each article.

Each line is taken as the pathname to a Usenet article. If it is not an absolute pathname, it is taken relative to the spool directory, `/news/spool`. (Only the first word of each line is parsed; anything following whitespace is ignored.)

The `-w` flag specifies how each output line should be written. The `items` for this flag should be chosen from the `w` flag items as specified in `newsfeeds(5)`. They may be chosen from the following set:

<code>b</code>	Size of article in bytes
<code>f</code>	Full pathname of article
<code>m</code>	Article Message-ID
<code>n</code>	Relative pathname of article

If the input file consists of a series of Message-IDs, then use `grehistory(1)` with the `-s` flag piped into `cvtbatch`.

HISTORY

Written by Rich Salz (`rsalz@uunet.uu.net`) for InterNetNews.

cytune

`cytune`—Tune Cyclades driver parameters.

SYNOPSIS

```
cytune [-q [-i interval]] ([-s value][[-S value]]
[-g|G] ([-t timeout][[-T timeout]]) tty [tty ...]
```

DESCRIPTION

`cytune` queries and modifies the interruption threshold for the Cyclades driver. Each serial line on a Cyclades card has a 12-byte FIFO for input (and another 12-byte FIFO for output). The “threshold” specifies how many input characters must be present in the FIFO before an interruption is raised. When a Cyclades `tty` is opened, this threshold is set to a default value based on baud rate:

<i>Baud</i>	<i>Threshold</i>
50-4800	10
9600	8
19200	4
38400	2
57600-150000	1

If the threshold is set too low, the large number of interruptions can load the machine and decrease overall system throughput. If the threshold is set too high, the FIFO buffer can overflow, and characters will be lost. Slower machines, however, may not be able to deal with the interrupt load and will require that the threshold be adjusted upwards.

If the Cyclades driver was compiled with `ENABLE_MONITORING` defined, the `cytune` command can be used with the `-q` option to report interrupts over the monitoring interval and characters transferred over the monitoring interval. It will also report

the state of the FIFO. The maximum number of characters in the FIFO when an interrupt occurred, the instantaneous count of characters in the FIFO, and how many characters are now in the FIFO are reported. This output might look like this:

```
/dev/cubC0: 830 ints, 9130 chars; fifo: 11 threshold, 11 max, 11 now
166.259866 interrupts/second, 1828.858521 characters/second
```

This output indicates that for this monitoring period, the interrupts were always being handled within one character time because `max` never rose above `threshold`. This is good, and you can probably run this way, provided that a large number of samples come out this way. You will lose characters if you overrun the FIFO because the Cyclades hardware does not seem to support the RTS RS-232 signal line for hardware flow control from the DCE to the DTE.

`cytune` will in query mode produce a summary report when ended with a `SIGINT` or when the threshold or time-out is changed.

There may be a responsiveness versus throughput tradeoff. The Cyclades card, at the higher speeds, is capable of putting a very high interrupt load on the system. This will reduce the amount of CPU time available for other tasks on your system. However, the time it takes to respond to a single character may be increased if you increase the threshold. This might be noticed by monitoring `ping(8)` times on a SLIP link controlled by a Cyclades card. If your SLIP link is generally used for interactive work such as `telnet(1)`, you might want to leave the threshold low so that characters are responded to as quickly as possible. If your SLIP link is generally used for file transfer, WWW, and the like, setting the FIFO to a high value is likely to reduce the load on your system while not significantly affecting throughput. Alternatively, see the `-t` or `-T` options to adjust the time that the Cyclades waits before flushing its buffer. Units are 5ms.

If you are running a mouse on a Cyclades port, it is likely that you want to maintain the threshold and time-out at a low value.

OPTIONS

- s *value* Set the current threshold to *value* characters. Note that if the `tty` is not being held open by another process, the threshold will be reset on the next open. Only values between 1 and 12, inclusive, are permitted.
- t *value* Set the current flush time-out to *value* units. Note that if the `tty` is not being held open by another process, the threshold will be reset on the next open. Only values between 0 and 255, inclusive, are permitted. Setting *value* to 0 forces the default, currently `0x20` (160ms) but soon to be `0x02` (10ms). Units are 5ms.
- g Get the current threshold and time-out.
- T *value* Set the default flush time-out to *value* units. When the `tty` is next opened, this value is used instead of the default. If *value* is 0, then the value defaults to `0x20` (160ms), soon to be `0x02` (10ms).
- G Get the default threshold and flush time-out values.
- q Gather statistics about the `tty`. The results are only valid if the Cyclades driver has been compiled with `ENABLE_MONITORING` defined. This is probably not the default.
- i *interval* Statistics will be gathered every *interval* seconds.

BUGS

If you run two copies of `cytune` at the same time to report statistics about the same port, the `ints`, `chars`, and `max` values will be reset and not reported correctly. `cytune(8)` should prevent this but does not.

debugfs

`debugfs`—`ext2` filesystem debugger.

SYNOPSIS

`debugfs` [`[-w]`] `device`

DESCRIPTION

`debugfs` is a filesystem debugger. It can be used to examine and change the state of an `ext2` filesystem. `device` is the special file corresponding to the device containing the `ext2` filesystem (such as `/dev/hdXX`).

OPTIONS

`-w`

Specify that the filesystem should be open in read-write mode. Without this option, the filesystem is open in read-only mode.

COMMANDS

`debugfs` is an interactive debugger. It understands a number of commands:

`cd file`

`chroot file`

`close`

`clrri file`

`expand_dir, file`

`find_free_block [goal]`

`find_free_inode [dir [mode]]`

`freeb block`

`freei file`

help

`iname inode`

`initialize device blocksize`

`kill_file file`

`ln source_file dest_file`

`ls [pathname]`

Modify_inode file

`mkdir file`

`open` [`[-w]`] `device`

`pwd`

`quit`

Close the currently open filesystem.

Clear the contents of the inode corresponding to `file`.

Expand a directory.

Find the first free block, starting from `goal`, and allocate it.

Find a free inode and allocate it.

Mark the block as not allocated.

Free the inode corresponding to `file`.

Print the filename corresponding to `inode` (currently not implemented).

Create an `ext2` file system on `device`.

Remove a file and deallocate its blocks.

Create a link.

Emulate the `ls(1)` command.

Modify the contents of the inode corresponding to `file`.

Make a directory.

Open a filesystem.

Quit `debugfs`.

<code>rm file</code>	Remove a file.
<code>rmdir file</code>	Remove a directory.
<code>setb block</code>	Mark the block as allocated.
<code>seti file</code>	Mark in use the inode corresponding to file
<code>show_super_stats</code>	List the contents of the super block.
<code>stat file</code>	Dump the contents of the inode corresponding to file.
<code>testb block</code>	Test if the block is marked as allocated.
<code>testi file</code>	Test if the inode corresponding to file is marked as allocated.
<code>unlink file</code>	Remove a link.

AUTHOR

`debugfs` was written by Theodore T'so (tytso@mit.edu).

Version 0.5b, November 1994

dip

`dip`—Dialup IP connection handler.

SYNOPSIS

```
dip [-t]
dip [-ktv] [-m mtu] scriptfile
dip [-iv] [user_name]
```

DESCRIPTION

`dip` handles the connections needed for dialup IP links, such as SLIP or PPP. It can handle both incoming and outgoing connections, using password security for incoming connections. The outgoing connections use the system's `dial(3)` library if available.

COMMAND MODE

The first possible use of `dip` is as a stand-alone program to set up an outgoing IP connection. This can be done by invoking `dip` with the `-t` option, which means enter TEST mode and, more precisely, dump you in the `COMMAND-MODE` of the `dip` program. You are reminded of this by the `DIP>` prompt, or, if you also specified the `-v` debugging flag, the `DIP [NNNN]>` prompt. The latter prompt also displays the current value of the global `errlvl` variable, which is used mostly when `dip` runs in script mode. For the interactive mode, it can be used to determine if the result of the previous command was okay.

The following is a sample taken from a live session:

```
$dip-t
DIP: Dialup IP Protocol Driver version 3.3.7 (12/13/93)
Written by Fred N. van Kempen, MicroWalt Corporation.
```

```
DIP>_
```

The most helpful command in this mode is, of course, the `help` command, which should produce an output similar to this:

```
DIP> help
DIP knows about the following commands:
```

```

databits default dial echo flush
get goto help if init
mode modem parity print port
reset send sleep speed stopbits
term wait

```

```
DIP>_
```

All commands display how they should be used when invoking them with no or invalid arguments. Just experiment a little to get the feel of it, and have a look at the sample script files, which also use this command language.

DIALIN MODE

The second possible way of using `dip` is as a login shell for incoming IP connections, as in dialup SLIP and PPP connections. To make integration into the existing UNIX system as easy as possible, `dip` can be installed as simply as using it as a login shell in the system's password file. A sample entry looks like

```
suunet:ij/SMxiTlGVC0:1004:10:UUNET:/tmp:/usr/bin/dip -i
```

When user `suunet` logs in, the `login(1)` program sets the home directory to `/tmp` and execute the `dip` program with the `-i` option, which means that `dip` must run in input mode. `dip` then tries to locate the name of the logged-in user (the name corresponding to its current user ID, as returned by the `getuid(2)` system call) in its database file. An optional single argument to the `dip` program in this mode can be the username that must be used in this lookup, regardless of the current user ID.

`dip` now scans the `/etc/net/diphosts` file for an entry for the given username. This file contains lines of text (much like the standard password file). The format looks like

```

#
# diphosts This file describes a number of name to
# address mappings for the DIP program. It
# is used to determine which IP address to
# use for in incoming call of some user.
#
# Version: @(#)diphosts 1.00 12/10/92 FvK
#
# Author: Fred N. van Kempen,
# <waltje@uwal.nl.mugnet.org>
#
suunet:uunet.uu.net:UUNET SLIP:SLIP,296

# End of diphosts.

```

The first field of a line identifies the username, which you must match. The second field can contain an encrypted password. If this field is non-null, the `dip` program asks for an external security password, which must match the password in this field. The third field contains the name (or raw IP address) of the host that is connecting to the system with this link. If a hostname is given, the usual address resolving process is started, using either a nameserver or a local hosts file.

The fourth field can contain any text; it is not (yet) used by the `dip` program. In future releases, this info may be used in the system log files. Finally, the fifth field of a line contains a mixture of comma-separated flags. Possible flags are

- SLIP to indicate you must use the SLIP protocol.
- PPP to indicate you must use the PPP protocol.
- number, which gives the MTU parameter of this connection.

After finding the correct line, `dip` puts the terminal line into RAW mode and asks the system networking layer to allocate a channel of the desired protocol. Finally, if the channel is activated, it adds an entry to the system's routing table to make the connection work.

dip now goes into an endless loop of sleeping, which continues until the connection is physically aborted (the line is dropped). At that time, dip removes the entry it made in the system's routing table and releases the protocol channel for reuse. It then exits, making room for another session.

DIALOUT MODE

The last way of using dip is as a program that initiates outgoing connections. To make life easier for the people who have to manage links of this type, dip uses a chat script to set up a link to a remote system. This gives the user an enormous amount of flexibility when making the connection, which otherwise could require many command-line options. The pathname of the script to be run is then given as the single argument to dip; the program will automatically check if the file has a filename ending in a .dip part. This is not mandatory—just a tool to group scripts together in a single directory. A script should look something like this:

```
#
# sample.dip Dialup IP connection support program.
# This file (should show) shows how to use the DIP
# scripting commands to establish a link to a host.
# This host runs the 386bsd operating system, and
# thus can only be used for the "static" addresses.
#
# NOTE: We also need an example of a script used to
# connect to a "dynamic" SLIP server, like an Annex
# terminal server...
#
# Version: @(#)sample.dip 1.30 07/05/93
#
# Author: Fred N. van Kempen, <waltje@uWalt.NL.Mugnet.ORG>
#
main:
# First of all, set up our name for this connection.
# I am called "uwalt.hacktic.nl" (== 193.78.33.238)
get $local uwalt.hacktic.nl
# Next, set up the other side's name and address.
# My dialin machine is called 'xs4all.hacktic.nl' (== 193.78.33.42)
get $remote xs4all.hacktic.nl
# Set the desired serial port and speed.
port cua0
speed 38400
# Reset the modem and terminal line.
# This seems to cause trouble for some people!
reset
# Prepare for dialing.
send ATQ0V1E1X1
wait OK 2
if $errlvl != 0 goto error
dial 555-1234567
if $errlvl != 0 goto error
wait CONNECT 60
if $errlvl != 0 goto error
# We are connected. Login to the system.
login:
sleep 3
send \r\n\r\n
wait ogin: 10
if $errlvl != 0 goto error
send NO-WAY\n
wait ord: 5
if $errlvl != 0 goto error
send HA-HA\n
```

```

wait $ 30
if $errlvl != 0 goto error
loggedin:
# We are now logged in. Start the 'sliplogin' program,
# as this is not automatically done for me.
send sliplogin\n
wait SOME-STRING 15
# Set up the SLIP operating parameters.
get $mtu 1500
# Set Destination net/address as type 'default' (vice an address).
# This is used by the 'route' command to set the kernel routing table.
# Some machines seem to require this be done for SLIP to work properly.
default
# Say hello and fire up!
done:
print CONNECTED to $remote with address $rmtip
mode SLIP
goto exit
error:
print SLIP to $remote failed.
exit:

```

This script causes `dip` to dial up a host, log in, and get a SLIP interface channel going (in the same manner as with incoming connections). When all is set up, it simply goes into the background and waits for a hangup (or just a lethal signal), at which it hangs up and exits.

FILES

```

/etc/passwd
/etc/diphosts

```

Version 3.3.7, 13 December 1993

dmmsg

`dmmsg`—Print or control the kernel ring buffer.

SYNOPSIS

```
dmmsg [ -c ] [ -n level ]
```

DESCRIPTION

`dmmsg` is used to examine or control the kernel ring buffer.

The program helps users to print their bootup messages. Instead of copying the messages by hand, the user need only

```
dmmsg > boot.messages
```

and mail the `boot.messages` file to whoever can debug their problem.

OPTIONS

- c Clear the ring buffer contents after printing.
- n level Set the level at which logging of messages is done to the console. For example, -n 1 prevents all messages, except panic messages, from appearing on the console. All levels of messages are still written to `/proc/kmsg`, so `syslogd(8)` can still be used to control exactly where kernel messages appear. When the -n option is used, `dmesg` will not print or clear the kernel ring buffer.

When both options are used, only the last option on the command line will have an effect.

Linux 0.99, 28 October 1993

dumpe2fs

`dumpe2fs`—Dump filesystem information.

SYNOPSIS

`dumpe2fs` `device`

DESCRIPTION

`dumpe2fs` prints the super block and blocks group information for the filesystem present on device.

`dumpe2fs` is similar to Berkeley's `dumpfs` program for the BSD Fast File System.

BUGS

You need to know the physical filesystem structure to understand the output.

AUTHOR

`dumpe2fs` was written by Remy Card (card@masi.ibp.fr), the developer and maintainer of the `ext2fs`.

AVAILABILITY

`dumpe2fs` is available for anonymous FTP from `ftp.ibp.fr` and `tsx-11.mit.edu` in `/pub/linux/packages/ext2fs`.

Version 0.5b, November 1994

e2fsck

`e2fsck`—Check a Linux second extended filesystem.

SYNOPSIS

`e2fsck` [`-panyrdfvvtFV`] [`-b` `superblock`] [`-B` `blocksize`]
 [`-l` | `-L` `bad_block_file`] `device`

DESCRIPTION

`e2fsck` is used to check a Linux second extended file system.

`device` The special file corresponding to the device (such as `/dev/hdXX`).

OPTIONS

<code>-a</code>	This option does the same thing as the <code>-p</code> option. It is provided for backwards compatibility only; it is suggested that people use <code>-p</code> option whenever possible.
<code>-b superblock</code>	Instead of using the normal superblock, use the alternative superblock specified by <code>superblock</code> .
<code>-B blocksize</code>	Usually, <code>e2fsck</code> will search for the superblock at various different block sizes in an attempt to find the appropriate block size. This search can be fooled in some cases. This option forces <code>e2fsck</code> to only try locating the superblock at a particular <code>blocksiz</code> . If the superblock is not found, <code>e2fsck</code> will terminate with a fatal error.
<code>-d</code>	Print debugging output (useless unless you are debugging <code>e2fsck</code>).
<code>-f</code>	Force checking even if the filesystem seems clean.
<code>-F</code>	Flush the filesystem device's buffer caches before beginning. Only really useful for doing <code>e2fsck</code> time trials.
<code>-l filename</code>	Add the blocks listed in the file specified by <code>filename</code> to the list of bad blocks.
<code>-L filename</code>	Set the bad blocks list to be the list of blocks specified by <code>filename</code> . (This option is the same as the <code>-l</code> option except the bad blocks list is cleared before the blocks listed in the file are added to the bad blocks list.)
<code>-n</code>	Open the filesystem read-only, and assume an answer of "no" to all questions. Allows <code>e2fsck</code> to be used non-interactively. (Note: if the <code>-l</code> or <code>-L</code> options are specified in addition to the <code>-n</code> option, then the filesystem will be opened read-write to permit the bad-blocks list to be updated. However, no other changes will be made to the filesystem.)
<code>-p</code>	Automatically repair ("preen") the filesystem without any questions.
<code>-r</code>	This option does nothing at all; it is provided only for backwards compatibility.
<code>-t</code>	Print timing statistics for <code>e2fsck</code> . If this option is used twice, additional timing statistics are printed on a pass-by-pass basis.
<code>-v</code>	Verbose mode.
<code>-V</code>	Print version information and exit.
<code>-y</code>	Assume an answer of "yes" to all questions; allows <code>e2fsck</code> to be used non-interactively.

EXIT CODE

The exit code returned by `e2fsck` is the sum of the following conditions:

0	No errors
1	Filesystem errors corrected
2	Filesystem errors corrected; system should be rebooted if filesystem was mounted
4	Filesystem errors left uncorrected
8	Operational error
16	Usage or syntax error
128	Shared library error

BUGS

Almost any piece of software will have bugs. If you manage to find a filesystem that causes `e2fsck` to crash, or that `e2fsck` is unable to repair, please report it to the author.

Please include as much information as possible in your bug report. Ideally, include a complete transcript of the `e2fsck` run, so I can see exactly what error messages are displayed. If you have a writeable filesystem where the transcript can be stored, the `script(1)` program is a handy way to save the output of `e2fsck` to a file.

It is also useful to send the output of `dumpe2fs(8)`. If a specific inode or inodes seems to be giving `e2fsck` trouble, try running the `debugfs(8)` command and send the output of the `stat` command run on the relevant inodes. If the inode is a directory, the `debugfs dump` command will allow you to extract the contents of the directory inode, which can sent to me after being first run through `uuencode(1)`.

Always include the full version string that `e2fsck` displays when it is run so I know which version you are running.

AUTHOR

This version of `e2fsck` is written by Theodore Ts'o (`tytso@mit.edu`).

Version 0.5b, November 1994

edquota

edquota—Edit user quotas.

SYNOPSIS

```
/usr/etc/edquota [ -p proto-user ][ -ug ] name...
/usr/etc/edquota [ -ug ] -t
```

DESCRIPTION

`edquota` is a quota editor. One or more users or groups may be specified on the command line. For each user or group, a temporary file is created with an ASCII representation of the current disk quotas for that user or group and an editor is then invoked on the file. The quotas may then be modified, new quotas added, and so on. Upon leaving the editor, `edquota` reads the temporary file and modifies the binary quota files to reflect the changes made.

The editor invoked is `vi(1)` unless the environment variable specifies otherwise.

Only the superuser may edit quotas. (For quotas to be established on a filesystem, the root directory of the filesystem must contain a file, owned by root, called `quota.user` or `quota.group`. See `quotaon(8)` for details.)

OPTIONS

-u	Edit the userquota. This is the default.
-g	Edit the groupquota.
-p	Duplicate the quotas of the prototypical user specified for each user specified. This is the normal mechanism used to initialize quotas for groups of users.
-t	Edit the soft time limits for each filesystem. If the time limits are zero, the default time limits in <code><linux/quota.h></code> are used. Time units of <code>sec(onds)</code> , <code>min(utes)</code> , <code>hour(s)</code> , <code>day(s)</code> , <code>week(s)</code> , and <code>month(s)</code> are understood. Time limits are printed in the greatest possible time unit such that the value is greater than or equal to one.

FILES

quota.user or quota.group	Quota file at the filesystem root
/etc/mtab	Mounted filesystems

SEE ALSO

quota(1), vi(1), quotactl(2), quotacheck(8), quotaon(8), repquota(8)

BUGS

The format of the temporary file is inscrutable.

8 June 1993

expire

`expire`—Usenet article and history expiration program.

SYNOPSIS

```
expire [ -d dir ] [-f file ] [-g file ] [-h file ]
[-i ] [-l ] [-n ] [-p ] [-q ] [-r reason ] [-s ] [-t ]
[-v level ] [-w number ] [-x ] [-z file ] [expirectl]
```

DESCRIPTION

`expire` scans the `history(5)` text file `/news/lib/history` and uses the information recorded in it to purge old news articles. To specify an alternate history file, use the `-f` flag. To specify an alternate input text history file, use the `-h` flag. `expire` uses the old `dbz(3z)` database to determine the size of the new one. To ignore the old database, use the `-i` flag.

`expire` usually just unlinks each file if it should be expired. If the `-l` flag is used, then all articles after the first one are treated as if they could be symbolic links to the first one. In this case, the first article will not be removed as long as any other cross-posts of the article remain.

`expire` usually sends a pause command to the local `innd(8)` daemon when it needs exclusive access to the history file, using the string `Expiring` as the reason. To give a different reason, use the `-r` flag. The process ID will be appended to the reason. When `expire` is finished and the new history file is ready, it sends a `go` command. If `innd` is not running, use the `-n` flag and `expire` will not send the pause or `go` commands. (For more details on the commands, see `ctlinnd(8)`.) Note that `expire` only needs exclusive access for a very short time—long enough to see if any new articles arrived since it first hit the end of the file and to rename the new files to the working files.

If the `-s` flag is used, then `expire` will print a summary when it exits, showing the approximate number of kilobytes used by all deleted articles.

If the `-t` flag is used, then `expire` will generate a list of the files that should be removed on its standard output, and the new history file will be left in `history.n`, `history.n.dir`, and `history.n.pag`. This flag is useful for debugging when used with the `-n` and `-s` flags. Note that if the `-f` flag is used, then the name specified with that flag will be used instead of `history`.

If the `-x` flag is used, then `expire` will not create any new history files. This is most useful when combined with the `-n`, `-s`, and `-t` flags to see how different expiration policies would change the amount of disk space used.

If the `-z` flag is used, then articles are not removed, but their names are written to the specified file. See the description of `expirerm` in `news.daily(8)`.

`expire` makes its decisions on the time the article arrived, as found in the history file. This means articles are often kept a little longer than with other expiration programs that base their decisions on the article's posting date. To use the article's posting date, use the `-p` flag. Use the `-w` flag to “warp” time so that `expire` thinks it is running at some time other than the current time. The value should be a signed floating-point number of the number of days to use as the offset.

If the `-d` flag is used, then the new history file and database is created in the specified directory, `dir`. This is useful when the filesystem does not have sufficient space to hold both the old and new history files. When this flag is used, `expire` leaves the server paused and creates a zero-length file named after the new history file, with an extension of `.done` to indicate that it has successfully completed the expiration. The calling script should install the new history file and unpauses the server. The `-r` flag should be used with this flag.

If a filename is specified, it is taken as the control file and parsed according to the rules in `expire.ct1(5)`. A single dash (`-`) may be used to read the file from standard input. If no file is specified, the file `/news/lib/expire.ct1` is read.

`expire` usually complains about articles that are posted to newsgroups not mentioned in the active file. To suppress this action, use the `-q` flag.

The `-v` flag is used to increase the verbosity of the program, generating messages to standard output. The level should be a number, where higher numbers result in more output. Level one will print totals of the various actions done (not valid if a new history file is not written), level two will print report on each individual file, and level five results in more than one line of output for every line processed. If the `-g` flag is given, then a one-line summary equivalent to the output of `-v1` and preceded by the current time will be appended to the specified file.

expireover

`expireover`—Expire entries from the news overview database.

SYNOPSIS

```
expireover [ -a ][-D overviewdir ][-f file ][-n ]
[-O overview.fmt ][-s ][-v ][-z ][file... ]
```

DESCRIPTION

`expireover` expires entries from the news overview database. It reads a list of pathnames (relative to the spool directory, `/news/spool`) from the specified files or standard input if none are specified. (A filename of `-` may be used to specify the standard input.) It then removes any mention of those articles from the appropriate overview database. If the `-z` flag is used, then the input is assumed to be sorted such that all entries for a newsgroup appear together so that it can be purged at once. This flag can be useful when used with the sorted output of `expire(8)`'s `-z` flag.

If the `-s` flag is used, then `expireover` will read the spool directory for all groups mentioned in the `active(5)` file and remove the overview entries for any articles that do not appear. To specify an alternate file, use the `-f` flag; a name of `-` is taken to mean the standard input.

The `-a` flag reads the spool directory and adds any missing overview entries. It will create files if necessary. This can be used to initialize a database or to sync up a overview database that may be lacking articles due to a crash. `overchan` should be running, to ensure that any incoming articles get included. Using this flag implies the `-s` flag; the `-f` flag may be used to add only a subset of the newsgroups.

To see a list of the entries that would be added or deleted, use the `-v` flag. To perform no real updates, use the `-n` flag.

The `-D` flag can be used to specify where the databases are stored. The default directory is `/news/spool`.

The `-O` flag may be used to specify an alternate location for the `overview.fmt(5)` file; this is usually only useful for debugging.

fastrm

fastrm—Quickly remove a set of files.

SYNOPSIS

```
fastrm [ -d ][ -e ][ -uN ][ -sM ][ -cI ] base_directory
```

DESCRIPTION

fastrm reads a list of files, one per line, from its standard input and removes them. If a file is not an absolute pathname, it is taken relative to the directory specified on the command line. The base directory parameter must be a simple absolute pathname—that is, it must not contain any `./` or `../` references.

fastrm is designed to be faster than the typical `| xargs rm` pipeline. For example, **fastrm** will usually `chdir(2)` into a directory before removing files from it. If the input is sorted, this means that most files to be removed will be simple names.

fastrm assumes that its input is valid and that it is safe to just do an `unlink(2)` call for each item to be removed. As a safety measure, if **fastrm** is run by root, it will first `stat(2)` the item to make sure that it is not a directory before unlinking it.

If the `-d` flag is used, then no files are removed. Instead, a list of the files to be removed, in debug form, is printed on the standard output. Each line contains either the current directory of **fastrm** at the time it would do the unlink and then the pathname it would pass to `unlink(2)` as two fields separated by white space and a `/` or the absolute pathname (a single field) of files it would unlink using the absolute pathname.

If the `-e` flag is used, **fastrm** will treat an empty input file (`stdin`) as an error. This is most useful when **fastrm** is last in a pipeline after a preceding `sort(1)` because if the sort fails, there will usually be no output to become input of **fastrm**.

If the `-u` flag is used, then **fastrm** makes further assumptions about its work environment—in particular, that there are no symbolic links in the target tree. This flag also suggests that it is probably faster to reference the path `../../../../` rather than start from the root and come down (note that this probably isn't true on systems that have a `namei` cache, which usually holds everything except `..`). The optional `N` is an integer that specifies the maximum number of `..` segments to use—paths that would use more than this use the absolute pathname (from the root) instead. If the `-u` flag is given without a value, `-u1` is assumed.

If the `-s` flag is used, then **fastrm** will perform the unlinks from one directory—that is, when a group of files in one directory appear in the input consecutively—in the order that the files appear in the directory from which they are to be removed. The intent of this flag is that on systems that have a per-process directory cache, finding files in the directory should be faster. It can have smaller benefits on other systems. The optional `M` is an integer that specifies the number of files that must be going to be removed from one directory before the files will be ordered. If the `-s` flag is given without a value, `-s5` is assumed. When the directory reordering is in use, **fastrm** will avoid attempting to unlink files that it can't see in the directory, which can speed it appreciably when many of the filenames have already been removed.

The `-c` flag may be given to instruct **fastrm** when it should `chdir(2)`. If the number of files to be unlinked from a directory is at least `I`, then **fastrm** will `chdir` and unlink the files from in the directory. Otherwise, it will build a path relative to its current directory. If `-c` is given without the optional integer `I`, then `-c1` is assumed, which will cause **fastrm** to always use `chdir`. If `-c` is not used at all, then `-c3` is assumed. Use `-c0` to prevent **fastrm** from ever using `chdir(2)`.

There are also `-a` and `-r` options, which do nothing at all except allow you to say `fastrm -usa`, `fastrm -ussr`, or `fastrm -user`. These happen to often be convenient sets of options to use.

`fastrm` exits with a status of 0 if there were no problems or 1 if something went wrong. Attempting to remove a file that does not exist is not considered a problem. If the program exits with a nonzero status, it is probably a good idea to feed the list of files into an `xargs rm` pipeline.

fdformat

`fdformat`—Low-level formats a floppy disk.

SYNOPSIS

```
fdformat [ -n ] device
```

DESCRIPTION

`fdformat` does a low-level format on a floppy disk. `device` is usually one of the following (for floppy devices, the major is 2, and the minor is shown for informational purposes only):

```
/dev/fd0d360 (minor = 4)
/dev/fd0h1200 (minor = 8)
/dev/fd0D360 (minor = 12)
/dev/fd0H360 (minor = 12)
/dev/fd0D720 (minor = 16)
/dev/fd0H720 (minor = 16)
/dev/fd0h360 (minor = 20)
/dev/fd0h720 (minor = 24)
/dev/fd0H1440 (minor = 28)
/dev/fd1d360 (minor = 5)
/dev/fd1h1200 (minor = 9)
/dev/fd1D360 (minor = 13)
/dev/fd1H360 (minor = 13)
/dev/fd1D720 (minor = 17)
/dev/fd1H720 (minor = 17)
/dev/fd1h360 (minor = 21)
/dev/fd1h720 (minor = 25)
/dev/fd1H1440 (minor = 29)
```

The generic floppy devices, `/dev/fd0` and `/dev/fd1`, will fail to work with `fdformat` when a non-standard format is being used or if the format has not been autodetected earlier. In this case, use `setfdprm(8)` to load the disk parameters.

OPTIONS

`-n` No verify. This option will disable the verification that is performed after the format.

SEE ALSO

`fd(4)`, `setfdprm(8)`, `mkfs(8)`, `emkfs(8)`

AUTHOR

Linux 0.99, 1 February 1993

fdisk

`fdisk`—Partition table manipulator for Linux.

SYNOPSIS

```
fdisk [ -l ] [ -v ] [ -s partition ] [ device ]
```

DESCRIPTION

`fdisk` is a menu-driven program for manipulation of the hard disk partition table. The device is usually one of the following:

```
/dev/hda
/dev/hdb
/dev/sda
/dev/sdb
```

The partition is a device name followed by a partition number. For example, `/dev/hda1` is the first partition on the first hard disk in the system.

If possible, `fdisk` will obtain the disk geometry automatically. This is not necessarily the physical disk geometry but is the disk geometry that MS-DOS uses for the partition table. If `fdisk` warns you that you need to set the disk geometry, please believe this statement and set the geometry. This should only be necessary with certain SCSI host adapters (the drivers for which are rapidly being modified to provide geometry information automatically).

Whenever a partition table is printed, a consistency check is performed on the partition table entries. This check verifies that the physical and logical start and end points are identical and that the partition starts and ends on a cylinder boundary (except for the first partition).

Old versions of `fdisk` (all versions prior to 1.1r including 0.93) incorrectly mapped the `cylinder/head/sector` specification onto absolute sectors. This might result in the first partition on a drive failing the consistency check. If you use LILO to boot, this situation can be ignored. However, there are reports that the OS/2 boot manager will not boot a partition with inconsistent data.

Some versions of MS-DOS create a first partition that does not begin on a cylinder boundary but on sector 2 of the first cylinder. Partitions beginning in cylinder 1 cannot begin on a cylinder boundary, but this is unlikely to cause difficulty unless you have OS/2 on your machine.

In version 1.1r, a `BLKRRPART ioctl()` is performed before exiting when the partition table is updated. This is primarily to ensure that removable SCSI disks have their partition table information updated. If the kernel does not update its partition table information, `fdisk` warns you to reboot. If you do not reboot your system after receiving such a warning, you might lose or corrupt the data on the disk. Sometimes `BLKRRPART` fails silently; when installing Linux, you should always reboot after editing the partition table.

DOS 6.X WARNING

The DOS `6.X FORMAT` command looks for some information in the first sector of the data area of the partition and treats this information as more reliable than the information in the partition table. `DOS FORMAT` expects `DOS FDISK` to clear the first 512 bytes of the data area of a partition whenever a size change occurs. `DOS FORMAT` will look at this extra information even if the `/U` flag is given

We consider this a bug in DOS `FORMAT` and DOS `FDISK`.

The bottom line is that if you use `cfdisk` or `fdisk` to change the size of a DOS partition table entry, then you must also use `dd` to zero the first 512 bytes of that partition before using `DOS FORMAT` to format the partition. For example, if you were using `cfdisk` to make a DOS partition table entry for `/dev/hda1`, then (after exiting `fdisk` or `cfdisk` and rebooting Linux so that the partition table information is valid) you would use the command `dd if=/dev/zero of=/dev/hda1 bs=512 count=1` to zero the first 512 bytes of the partition.

Be extremely careful if you use the `dd` command because a small typo can make all of the data on your disk useless.

For best results, you should always use an OS-specific partition table program. For example, you should make DOS partitions with the `DOS FDISK` program and Linux partitions with the Linux `fdisk` or Linux `cfdisk` program.

OPTIONS

<code>-v</code>	Prints version number of <code>fdisk</code> program.
<code>-l</code>	Lists the partition tables for <code>/dev/hda</code> , <code>/dev/hdb</code> , <code>/dev/sda</code> , <code>/dev/sdb</code> , <code>/dev/sdc</code> , <code>/dev/sdd</code> , <code>/dev/sde</code> , <code>/dev/sdf</code> , <code>/dev/sdg</code> , and <code>/dev/sdh</code> and then exits.
<code>-s partition</code>	If the <code>partition</code> is not a DOS partition (the partition ID is greater than 10), then the size of that partition is printed on the standard output. This value is usually used as an argument to the <code>mkfs(8)</code> program to specify the size of the partition that will be formatted.

BUGS

Although this man page (written by `faith@cs.unc.edu`) is poor, there is excellent documentation in the `README.fdisk` file (written by `LeBlanc@mcc.ac.uk`) that should always be with the `fdisk` distribution. If you cannot find this file in the `util-linux-*` directory or with the `fdisk.c` source file, then you should write to the distributor of your version of `fdisk` and complain that you do not have all of the available documentation.

AUTHOR

A.V. LeBlanc (`LeBlanc@mcc.ac.uk`). v1.0r: SCSI and `extfs` support added by Rik Faith (`faith@cs.unc.edu`). v1.1r: Bug fixes and enhancements by Rik Faith (`faith@cs.unc.edu`), with special thanks to Michael Bischoff (`i1041905@ws.rz.tu-bs.de` or `mbi@mo.math.nat.tu-bs.de`). v1.3: Latest enhancements and bug fixes by A.V. LeBlanc, including the addition of the `-s` option. v2.0: Disks larger than 2GB are now fully supported, thanks to Remy Card's `llseek` support.

Linux 1.0, 3 June 1995

filechan

`filechan`—File-writing back end for InterNetNews.

SYNOPSIS

```
filechan [ -d directory ] [-f fields ] [-m mapfile ] [-p pifile ]
```

DESCRIPTION

`filechan` reads lines from standard input and copies certain fields in each line into files named by other fields within the line. `filechan` is intended to be called by `inn(8)` as a channel feed. (It is not a full exploder and does not accept commands; see `newsfeeds(5)` for a description of the difference and `buffchan(8)` for an exploder program.)

`filechan` input is interpreted as a set of lines. Each line contains a fixed number of initial fields, followed by a variable number of filename fields. All fields in a line are separated by whitespace. The default number of initial fields is one; the `-f` flag may be used to specify a different number of fields.

For each line of input, `filechan` writes the initial fields, separated by whitespace and followed by a newline, to each of the files named in the `filename` fields. When writing to a file, `filechan` opens it in append mode and tries to lock it and change the ownership to the user and group who owns the directory where the file is being written.

By default, `filechan` writes its arguments into the directory `/news/spool/out.going`. The `-d` flag may be used to specify a directory the program should change to before starting.

If the `-p` flag is used, the program will write a line containing its process ID (in text) to the specified file.

If `filechan` is invoked with `-f 2` and given the following input:

```
news/software/b/132 <1643@munnnari.oz.au>foo uunet
news/software/b/133 <102060@litchi.foo.com> uunet munnnari
comp/sources/unix/2002 <999@news.foo.com>foo uunet munnnari
```

Then the file `foo` will have these lines:

```
news/software/b/132 <1643@munnnari.oz.au>
comp/sources/unix/2002 <999@news.foo.com>
```

The file `munnnari` will have these lines:

```
news/software/b/133 <102060@litchi.foo.com>
comp/sources/unix/2002 <999@news.foo.com>
```

The file `uunet` will have these lines:

```
news/software/b/132 <1643@munnnari.oz.au>
news/software/b/133 <102060@litchi.foo.com>
comp/sources/unix/2002 <999@news.foo.com>
```

Because the time window in which a file is open is very small, complicated flushing and locking protocols are not needed; a `mv(1)` followed by a `sleep(1)` for a couple of seconds is sufficient.

A map file may be specified by using the `-m` flag. Blank lines and lines starting with a number sign (`#`) are ignored. All other lines should have two hostnames separated by a colon. The first field is the name that may appear in the input stream; the second field names the file to be used when the name in the first field appears. For example, the following map file may be used to map the short names to the full domain names:

```
# This is a comment uunet:news.uu.net foo:foo.com munnnari:munnnari.oz.au
```

HISTORY

Written by Robert Elz (`kre@munnnari.oz.au`); flags added by Rich Salz (`rsalz@uunet.uu.net`).

fsck

`fsck`—Check and repair a Linux filesystem.

SYNOPSIS

```
fsck [ -AVRTN ] [-s ] [-t fstype ] [fs-options ] filesys [ ... ]
```

DESCRIPTION

`fsck` is used to check and optionally repair a Linux filesystem. `filesystems` is either the device name (such as `/dev/hda1` or `/dev/sdb2`) or the mount point (such as `/`, `/usr`, or `/home`) for the filesystem. If this `fsck` has several filesystems on different physical disk drives to check, this `fsck` will try to run them in parallel. This reduces the total amount time it takes to check all of the filesystems because `fsck` takes advantage of the parallelism of multiple disk spindles.

The exit code returned by `fsck` is the sum of the following conditions:

0	No errors
1	Filesystem errors corrected
2	System should be rebooted
4	Filesystem errors left uncorrected
8	Operational error
16	Usage or syntax error
128	Shared library error

The exit code returned when all filesystems are checked using the `-A` option is the bitwise OR of the exit codes for each file system that is checked.

In actuality, `fsck` is simply a front end for the various filesystem checkers (`fsck.fstype`) available under Linux. The filesystem-specific checker is searched for in `/sbin` first, then in `/etc/fs` and `/etc`, and finally in the directories listed in the `PATH` environment variable. Please see the filesystem-specific checker manual pages for further details.

OPTIONS

<code>-A</code>	Walk through the <code>/etc/fstab</code> file and try to check all filesystems in one run. This option is typically used from the <code>/etc/rc</code> system initialization file, instead of multiple commands for checking a single file system.
<code>-R</code>	When checking all filesystems with the <code>-A</code> flag, skip the root file system (in case it's already mounted read-write).
<code>-T</code>	Don't show the title on startup.
<code>-N</code>	Don't execute; just show what would be done.
<code>-s</code>	Serialize <code>fsck</code> operations. This is a good idea if you checking multiple filesystems in and the checkers are in an interactive mode. (Note: <code>e2fsck</code> runs in an interactive mode by default. To make <code>e2fsck</code> run in a non-interactive mode, you must either specify the <code>-p</code> or <code>-a</code> option, if you want errors to be corrected automatically, or the <code>-n</code> option if you do not.)
<code>-V</code>	Produce verbose output, including all filesystem-specific commands that are executed.
<code>-tfstype</code>	Specifies the type of filesystem to be checked. When the <code>-A</code> flag is specified, only filesystems that match <code>fstype</code> are checked. If <code>fstype</code> is prefixed with <code>no</code> , only filesystems whose filesystem do not match <code>fstype</code> are checked. Usually, the filesystem type is deduced by searching for <code>filesystems</code> in the <code>/etc/fstab</code> file and using the corresponding entry. If the type can not be deduced, <code>fsck</code> will use the type specified by the <code>-t</code> option if it specifies a unique filesystem type. If this type is not available, the the default filesystem type (currently <code>ext2</code>) is used.
<code>fs-options</code>	Any options that are not understood by <code>fsck</code> , or that follow the <code>-</code> option are treated as filesystem-specific options to be passed to the filesystem-specific checker.

Currently, standardized filesystem-specific options are somewhat in flux. Although not guaranteed, the following options are supported by most filesystem checkers:

- a Automatically repair the filesystem without any questions. (Use this option with caution.) Note that `e2fsck` supports `-a` for backwards compatibility only. This option is mapped to `e2fsck`'s `-p` option, which is safe to use, unlike the `-a` option that most filesystem checkers support.
- r Interactively repair the filesystem (ask for confirmations). Note: It is generally a bad idea to use this option if multiple `fsck`'s are run in parallel. Also note that this is `e2fsck` default behavior; it supports this option for backwards compatibility reasons only.

AUTHOR

Theodore Ts'o (tytso@mit.edu)

The manual page was shamelessly adapted from David Engel and Fred van Kempen's generic `fsck` front-end program, which in turn was shamelessly adapted from Remy Card's version for the `ext2` filesystem.

FILES

`/etc/fstab`

Version 0.5b, November 1994

fsck.minix

`fsck.minix`—A filesystem consistency checker for Linux.

SYNOPSIS

```
fsck.minix [ -larvsmf ] device
```

DESCRIPTION

`fsck.minix` performs a consistency check for the Linux MINIX filesystem. The current version supports the 14 character and 30 character filename options.

The program assumes the filesystem is quiescent. `fsck.minix` should not be used on a mounted device unless you can be sure nobody is writing to it (and remember that the kernel can write to it when it searches for files).

The device will usually have the following form:

```
/dev/hda[1-8]
/dev/hdb[1-8]
/dev/sda[1-8]
/dev/sdb[1-8]
```

If the filesystem was changed (that is, repaired), then `fsck.minix` will print `File system has changed and will sync(2)` three times before exiting. Because Linux does not currently have raw devices, there is no need to reboot at this time (versus a system that does have raw devices).

WARNING

`fsck.minix` should not be used on a mounted filesystem. Using `fsck.minix` on a mounted filesystem is very dangerous due to the possibility that deleted files are still in use and can seriously damage a perfectly good filesystem! If you absolutely have to run `fsck.minix` on a mounted filesystem (that is, the root filesystem), make sure nothing is writing to the disk and that no files are "zombies" waiting for deletion.

OPTIONS

-l	Lists all filenames.
-r	Performs interactive repairs.
-a	Performs automatic repairs (this option implies <code>-r</code>) and serves to answer all of the questions asked with the default. Note that this can be extremely dangerous in the case of extensive filesystem damage.
-v	Verbose.
-s	Outputs super-block information.
-m	Activates MINIX-like “mode not cleared” warnings.
-f	Force filesystem check even if the filesystem was marked as valid. (This marking is done by the kernel when the filesystem is unmounted.)

SEE ALSO

`fsck(8)`, `fsck.ext(8)`, `fsck.ext2(8)`, `fsck.xiafs(8)`, `mkfs(8)`, `mkfs.minix(8)`, `mkfs.ext(8)`, `mkfs.ext2(8)`, `mkfs.xiafs(8)`, `reboot(8)`

DIAGNOSTICS

There are numerous diagnostic messages. The ones mentioned here are the most commonly seen in normal usage.

If the device does not exist, `fsck.minix` will print `Unable to read super block`. If the device exists but is not a MINIX filesystem, `fsck.minix` will print `Bad magic number in super-block`.

EXIT CODES

The exit code returned by `fsck.minix` is the sum of the following:

0	No errors.
3	Filesystem errors corrected; system should be rebooted if filesystem was mounted.
4	Filesystem errors left uncorrected.
8	Operational error.
16	Usage or syntax error.

In point of fact, only 0, 3, 4, 7, 8, and 16 can ever be returned.

AUTHOR

Linus Torvalds (torvalds@cs.helsinki.fi). Error code values by Rik Faith (faith@cs.unc.edu). Added support for filesystem valid flag: Dr. Wettstein (greg@wind.uucp@plains.nodak.edu). Check to prevent `fsck` of mounted filesystem added by Daniel Quinlan (quinlan@yggdrasil.com).

Linux 0.99, 10 January 1994

ftpd

ftpd—DARPA Internet File Transfer Protocol server.

SYNOPSIS

```
ftpd [-d] [-l] [-t timeout] [-T maxtimeout]
```

DESCRIPTION

ftpd is the DARPA Internet File Transfer Protocol server process. The server uses the TCP protocol and listens at the port specified in the FTP service specification; see `services(5)`.

Available options:

- d Debugging information is written to the syslog.
- l Each FTP 1 session is logged in the syslog.
- t The inactivity timeout period is set to timeout seconds. (The default is 15 minutes.)
- T A client can also request a different timeout period; the maximum period allowed can be set to timeout seconds with the -T option. The default limit is 2 hours.

The FTP server currently supports the following FTP requests; case is not distinguished.

<i>Request</i>	<i>Description</i>
ABOR	Abort previous command
ACCT	Specify account (ignored)
ALLO	Allocate storage (vacuously)
APPE	Append to a file
CDUP	Change to parent of current working directory
CWD	Change working directory
DELE	Delete a file
HELP	Give help information
LIST	Give list files in a directory ('' 1s -lgA '')
MKD	Make a directory
MDTM	Show last modification time of file
MODE	Specify data transfer mode
NLST	Give name list of files in directory
NOOP	Do nothing
PASS	Specify password
PASV	Prepare for server-to-server transfer
PORT	Specify data connection port
PWD	Print the current working directory
QUIT	Terminate session
REST	Restart incomplete transfer
RETR	Retrieve a file
RMD	Remove a directory
RNFR	Specify rename-from filename
RNTO	Specify rename-to filename
SITE	Nonstandard commands (see next section)
SIZE	Return size of file
STAT	Return status of server
STOR	Store a file
STOU	Store a file with a unique name
STRU	Specify data transfer structure
SYST	show operating system type of server system
TYPE	specify data transfer type
USER	specify username
XCUP	change to parent of current working directory (deprecated)

<i>Request</i>	<i>Description</i>
XPWD	change working directory (deprecated)
XMKD	make a directory (deprecated)
XPWD	print the current working directory (deprecated)
XRMD	remove a directory (deprecated)

The following non-standard or UNIX-specific commands are supported by the `SITE` request:

<i>Request</i>	<i>Description</i>	<i>Example</i>
UMASK	Change umask	<code>SITE UMASK 002</code>
IDLE	Set idle timer	<code>SITE IDLE 60</code>
CHMOD	Change mode of a file	<code>SITE CHMOD 755</code>
HELP	Give help information	<code>SITE HELP</code>

The remaining FTP requests specified in Internet RFC 959 are recognized but not implemented. `MDTM` and `SIZE` are not specified in RFC 959 but will appear in the next updated FTP RFC.

The FTP server will abort an active file transfer only when the `ABOR` command is preceded by a Telnet “Interrupt Process” (IP) signal and a Telnet “Synch” signal in the command Telnet stream, as described in Internet RFC 959. If a `STAT` command is received during a data transfer, preceded by a Telnet IP and `Synch`, transfer status will be returned.

`ftpd` interprets filenames according to the globbing conventions used by `csh(1)`. This allows users to utilize the metacharacters `Li & *?[]`.

`ftpd` authenticates users according to four rules:

- The username must be in the password database and not have a null password. In this case, a password must be provided by the client before any file operations may be performed.

- The username must not appear in the file (see `ftpusers(5)`).

- The user must have a standard shell returned by `getusershell(3)`.

- If the username is anonymous or FTP, an anonymous FTP account must be present in the password file (user FTP). In this case, the user is allowed to log in by specifying any password. (By convention, this is given as the client host’s name.)

In the last case, `ftpd` takes special measures to restrict the client’s access privileges. The server performs a `chroot(2)` command to the home directory of the FTP user. So that system security is not breached, it is recommended that the FTP subtree be constructed with care; the following rules are recommended:

<code>~ftp</code>	Make the home directory owned by root and unwritable by anyone.
<code>~ftp/bin</code>	Make this directory owned by root and unwritable by anyone. The program <code>ls(1)</code> must be present to support the <code>list</code> command. This program should have mode <code>111</code> .
<code>~ftp/etc</code>	Make this directory owned by root and unwritable by anyone. The files <code>passwd(5)</code> and <code>group(5)</code> must be present for the <code>ls</code> command to be able to produce owner names rather than numbers. The password field in <code>passwd</code> is not used and should not contain real encrypted passwords. These files should be mode <code>444</code> and owned by root. Don’t use the system’s <code>/etc/passwd</code> file as the password file or the system’s <code>/etc/group</code> file as the <code>group</code> file in the <code>~ftp/etc</code> directory.
<code>Pa ~ftp/pub</code>	Make this directory mode <code>755</code> and owned by root. Create a subdirectory in <code>~ftp/pub</code> with the appropriate mode (<code>777</code> or <code>733</code>) if you want to allow normal users to upload files.

SEE ALSO

`ftp(1)`, `getusershell(3)`, `ftpusers(5)`, `syslogd(8)`

BUGS

The anonymous account is inherently dangerous and should avoided when possible.

The server must run as the super-user to create sockets with privileged port numbers. It maintains an effective user ID of the logged-in user, reverting to the super-user only when binding addresses to sockets. The possible security holes have been extensively scrutinized but are possibly incomplete.

HISTORY

The command appeared in BSD 4.2.

BSD 4.2, 16 March 1991

ifconfig

`ifconfig`—Configure a network interface.

SYNOPSIS

```
ifconfig [interface]
ifconfig interface [aftype] options | address ...
```

DESCRIPTION

`ifconfig` is used to set up (and maintain thereafter) the kernel-resident network interfaces. It is used at boot time to configure most of them to a running state. After that, it is usually only needed when debugging or when system tuning is needed.

If no arguments are given, `ifconfig` just displays the status of the currently defined interfaces. If the single interface argument is given, it displays the status of the given interface only. Otherwise, it assumes that things have to be set up.

ADDRESS FAMILIES

If the first argument after the interface name is recognized as the name of a supported address family, that address family is used for decoding and displaying all protocol addresses. Currently supported address families include `inet` (TCP/IP, default) and `ax25` (AMPR Packet Radio.)

OPTIONS

<code>interface</code>	The name of the NET interface. This usually is a name such as <code>wd0</code> , <code>sl3</code> , or something like that: a device driver name followed by a unit number.
<code>up</code>	This flag causes the interface to be activated. It is implicitly specified if the interface is given a new address (see below).
<code>down</code>	This flag causes the driver for this interface to be shut down and is useful when things start going wrong.
<code>[-]arp</code>	Enable or disable the use of the ARP protocol on this interface. If the minus (-) sign is present, the flag is turned OFF.
<code>[-]trailers</code>	Enable or disable the use of trailers on Ethernet frames. This is not used in the current implementation of NET.
<code>[-]allmulti</code>	Enable or disable the promiscuous mode of the interface. This means that all incoming frames get sent to the network layer of the system kernel, allowing for networking monitoring.
<code>metric N</code>	This parameter sets the interface metric. It is not used at present, but we implement it for the future.
<code>mtu N</code>	This parameter sets the Maximum Transfer Unit (MTU) of an interface. For Ethernet, this is a number in the range of 1000-2000 (default is 1500). For SLIP, use something between 200 and 4096. Note that the current implementation does not handle IP fragmentation yet, so you'd better make the MTU large enough!
<code>dstaddr addr</code>	Set the "other end's" IP address in case of a point-to-point link, such as PPP. This keyword is obsolete by the new <code>pointopoint</code> keyword.

netmask <i>addr</i>	Set the IP network mask for this interface. This value defaults to the usual class A, B, or C network mask (as deducted from the interface IP address), but it can be set to any value for the use of subnetting.
[<i>-</i>]broadcast [<i>addr</i>]	If the address argument is also given, set the protocol broadcast address for this interface. Otherwise, it only sets the IFF_BROADCAST flag of the interface. If the keyword was preceded by a minus (-) sign, then the flag is cleared instead.
[<i>-</i>]pointopoint [<i>addr</i>]	This keyword enables the point-to-point mode of an interface, meaning that it is a direct link between two machines with nobody else listening on it. (At least we hope that this is the case, grin :-).) If the address argument is also given, set the protocol address of the other side of the link, just like the obsolete <i>dstaddr</i> keyword does. Otherwise, it only sets the IFF_POINTOPOINT flag of the interface. If the keyword was preceded by a minus (-) sign, then the flag is cleared instead.
hw	Set the hardware address of this interface if the device driver supports this operation. The keyword must be followed by the name of the hardware class and the printable ASCII equivalent of the hardware address. Hardware classes currently supported include <i>ether</i> (Ethernet), <i>ax25</i> (AMPR AX.25), and <i>ppp</i> , although the latter is not really supported yet.
address	The hostname or IP address (a hostname will be resolved into an IP address) of that interface. This parameter is required, although the syntax doesn't currently require it.

FILES

/dev/net/socket

BUGS

None so far, although the syntax checking could be better.

inetd

inetd—Internet superserver.

SYNOPSIS

```
inetd [-d] [configuration file]
```

DESCRIPTION

inetd should be run at boot time by */etc/rc.local* (see *rc(8)*). It then listens for connections on certain Internet sockets. When a connection is found on one of its sockets, it decides what service the socket corresponds to and invokes a program to service the request. After the program is finished, it continues to listen on the socket (except in some cases, which are described later). Essentially, *inetd* allows running one daemon to invoke several others, reducing load on the system.

The option available for *inetd*:

-d Turns on debugging.

Upon execution, *inetd* reads its configuration information from a configuration file, which, by default, is */etc/inetd.conf*. There must be an entry for each field of the configuration file, with entries for each field separated by a tab or a space. Comments are denoted by a # at the beginning of a line. There must be an entry for each field. The fields of the configuration file are as follows:

```

service name
socket type
protocol
wait/nowait[.max]
user[.group]
server program
server program arguments

```

To specify an Sun-RPC based service, the entry would contain these fields:

```

service name/version
socket type
rpc/protocol
wait/nowait[.max]
user[.group]
server program
server program arguments

```

The service-name entry is the name of a valid service in the file `/etc/services`. For internal services, the service name must be the official name of the service (that is, the first entry in `/etc/services`). When used to specify a Sun-RPC based service, this field is a valid RPC service name in the file `/etc/rpc`. The part on the right of the `/` is the RPC version number. This can simply be a single numeric argument or a range of versions. A range is bounded by the low version to the high version

```
- rusers/1-3.
```

The socket type should be one of `stream`, `dgram`, `raw`, `rdm`, or `seqpacket`, depending on whether the socket is a stream, datagram, raw, reliably delivered message, or sequenced packet socket.

The protocol must be a valid protocol as given in `/etc/protocols`. Examples might be `tcp` or `udp`. Rpc-based services are specified with the `rpc/tcp` or `rpc/udp` service type.

The wait/nowait entry is applicable to datagram sockets only. (Other sockets should have a nowait entry in this space.) If a datagram server connects to its peer, freeing the socket so `inetd` can receive further messages on the socket, it is said to be a multithreaded server and should use the nowait entry. For datagram servers that process all incoming datagrams on a socket and eventually time out, the server is said to be single-threaded and should use a wait entry. `Comsat(8)`, `biff(1)`, and `talkd(8)` are examples of the latter type of datagram server. `Tftpd(8)` is an exception; it is a datagram server that establishes pseudo-connections.

It must be listed as wait in order to avoid a race; the server reads the first packet, creates a new socket, and then forks and exits to allow `inetd` to check for new service requests to spawn new servers. The optional `max` suffix (separated from `wait` or `nowait` by a dot) specifies the maximum number of server instances that may be spawned from `inetd` within an interval of 60 seconds. When omitted, `max` defaults to 40.

The user entry should contain the username of the user as whom the server should run. This allows for servers to be given less permission than root. An optional group name can be specified by appending a dot to the username followed by the group name. This allows for servers to run with a different (primary) group ID than specified in the password file. If a group is specified and the user is not root, the supplementary groups associated with that user will still be set.

The server-program entry should contain the pathname of the program that is to be executed by `inetd` when a request is found on its socket. If `inetd` provides this service internally, this entry should be `internal`.

The server program arguments should appear just as arguments normally do, starting with `argv[0]`, which is the name of the program. If the service is provided internally, the word `internal` should take the place of this entry.

`inetd` provides several trivial services internally by use of routines within itself. These services are `echo`, `discard`, `chargen` (character generator), `daytime` (human readable time), and `time` (machine readable time in the form of the number of seconds since midnight, January 1, 1900). All of these services are TCP based. For details of these services, consult the appropriate RFC from the Network Information Center.

inetd rereads its configuration file when it receives a hangup signal, SIGHUP. Services may be added, deleted, or modified when the configuration file is reread. inetd creates a file `/etc/inetd.pid` that contains its process identifier.

HISTORY

The command appeared in BSD 4.3. Support for Sun-RPC based services is modeled after that provided by Sun-OS 4.1.

BSD 4.3, 16 March 1991

init, telinit

init, telinit—Process control initialization.

SYNOPSIS

```
/sbin/init [ -t sec ][0123456SsQq ]
/sbin/telinit [ -t sec ][0123456sSQqabc ]
```

DESCRIPTION

init

init is the father of all processes. Its primary role is to create processes from a script stored in the file `/etc/inittab` (see `inittab(5)`). This file usually has entries that cause init to spawn gettys on each line that users can log in. It also controls autonomous processes required by any particular system.

A run level is a software configuration of the system that allows only a selected group of processes to exist. The processes spawned by init for each of these run levels are defined in the `/etc/inittab` file. init can be in one of eight run levels, 06 and s or S. The run level is changed by having a privileged user run `/sbin/telinit`, which sends appropriate signals to init, telling it which run level to change to.

After init is invoked as the last step of the kernel booting, it looks for the file `/etc/inittab` to see if there is an entry of the type `initdefault` (see `inittab(5)`). `initdefault` determines the initial run level of the system. If there is no such entry or no `/etc/inittab` at all, a run level must be entered at the system console.

Run level s or S brings the system to single-user mode and does not require an `/etc/inittab` file. In single-user mode,

`/bin/sh` is invoked on `/dev/console`.

`/dev/console` need not necessarily be the physical system console. When init is told to enter single-user mode or run level 1 (either directly, by `init S`, or by telling shutdown to enter maintenance mode), it will link the terminal line the command was executed from to `/dev/console`. The device `/dev/systty` is called the physical system console and the device `/dev/console` is called the logical system console. If the logical system console is not the physical system console, pressing the combination `Ctrl+Alt+Del` on the physical system console will force a relink of `/dev/console` to `/dev/systty`. A terminal line can only become the logical console if it's listed in the file `/etc/securetty`. All this is in preparation of the day that the Linux kernel will support serial consoles.

Beware: If you want to run `x` or anything else that is aware of Virtual Consoles, the logical system console (`/dev/console`) needs to be the same as the physical system console (`/dev/systty`).

When entering single-user mode, init reads the console's `ioctl(2)` states from `/etc/ioctl.save`. If this file does not exist, init initializes the line at 9600 baud and with `CLOCAL` settings. When init leaves single-user mode, it stores the console's `ioctl` settings in this file so it can re-use them for the next single-user session. If the logical system console is changed to another terminal line, the settings of the line from which the `init` or `telinit` command was given are stored in `/etc/ioctl.save` too, so that the terminal line will be initialized correctly in single-user mode.

When entering a multi-user mode the first time, `init` performs the `boot` and `bootwait` entries to allow filesystems to be mounted before users can log in. Then all entries matching the run level are processed.

Each time a child terminates, `init` records the fact and the reason it died in `/etc/utmp` and `/var/adm/wtmp` if these files exist.

After it has spawned all the processes specified, `init` waits for one of its descendant processes to die, a powerfail signal, or a signal by `/sbin/telinit` to change the system's run level. When one of these three conditions occurs, it re-examines the `/etc/inittab` file. New entries can be added to this file at any time. However, `init` still waits for one of the three conditions to occur. To provide for an instantaneous response, the `Q` or `q` command can wake up `init` to re-examine the `/etc/inittab` file.

If `init` is not in single-user mode and receives a powerfail signal, special powerfail entries are invoked.

When `init` is requested to change the run level, it sends the warning signal `SIGTERM` to all processes that are undefined in the new run level. It then waits 20 seconds before forcibly terminating these processes via the kill signal `SIGKILL`.

Note that `init` assumes that all these processes (and their descendants) remain in the same process group that `init` originally created for them. If any process changes its process group affiliation, it will not receive these signals. Such processes need to be terminated separately.

telinit

`/sbin/telinit` is linked to `/sbin/init`. It takes a one-character argument and signals `init` to perform the appropriate action.

The following arguments serve as directives to `/sbin/telinit`:

<code>0, 1, 2, 3, 4, 5, or 6</code>	Tell <code>/sbin/init</code> to switch to the specified run level.
<code>a, b, c</code>	Tell <code>/sbin/init</code> to process only those <code>/etc/inittab</code> file entries having run level <code>a, b, or c</code> .
<code>Q or q</code>	Tell <code>/sbin/init</code> to re-examine the <code>/etc/inittab</code> file.
<code>S or s</code>	Tell <code>/sbin/init</code> to switch to single-user mode.

`/sbin/telinit` can also tell `init` how much time it should wait between sending processes the `TERM` and the `KILL` signal; the default is 20 seconds, but it can be changed by the `-t sec` option.

`/sbin/telinit` can be invoked only by users with appropriate privileges.

RUN LEVELS

Run levels `0, 1, and 6` are reserved. Run level `0` is used to halt the system, run level `6` is used to reboot the system, and run level `1` is used to get the system down into single-user mode. Run level `s` is not really meant to be used directly but should be used by scripts that are executed when entering run level `1`. For more information on this, see the man pages for `shutdown(1)` and `inittab(5)`.

FILES

```
/etc/inittab
/dev/console
/dev/systty
/etc/ioctl.save
/etc/utmp
/var/adm/wtmp
```

CONFORMING TO

`init` is compatible with the System V `init`. The scripts that are used with it, however, are mostly modeled after the BSD startup scripts. There are startup scripts available that let Linux boot more like a System V system, but most people find them too complex.

WARNINGS

`init` assumes that processes and descendants of processes remain in the same process group that was originally created for them. If the processes change their group, `init` can't kill them and you might end up with two processes reading from one terminal line.

DIAGNOSTICS

If `/sbin/init` finds that it is continuously respawning an entry more than ten times in two minutes, it will assume that there is an error in the command string, generate an error message on the system console, and refuse to respawn this entry until either five minutes has elapsed or it receives a signal. This prevents it from eating up system resources when someone makes a typographical error in the `/etc/inittab` file or the program for the entry is removed.

innd, inndstart

`innd`, `inndstart`—InterNetNews daemon.

SYNOPSIS

```
innd [ -a ][-c days ][-d ][-f ][-i count ][-o count ][-l size ]
[-m mode ][-n flag ] [ -p port ][-r ][-s ][-S host ][-t timeout ][-u ][-x ]
inndstart [ flags ]
```

DESCRIPTION

`innd`, the InterNetNews daemon, handles all incoming NNTP feeds. It reads the `active(5)`, `newsfeeds(5)`, and `hosts.nntp(5)` files into memory. It then opens the NNTP port to receive articles from remote sites, a UNIX-domain stream socket to receive articles from local processes such as `nnrpd(8)` and `rnews(1)`, and a UNIX-domain datagram socket for use by `ctlinnd(8)` to direct the server to perform certain actions. It also opens the `history(5)` database and two log files to replace its standard output and standard error. If the `-p` flag is used, then the NNTP port is assumed to be open on the specified descriptor. (If this flag is used, then `innd` assumes it is running with the proper permissions and it does not call `chown(2)` on any files or directories it creates.)

Once the files and sockets have been opened, `innd` waits for connections and data to be ready on its ports by using `select(2)` and non-blocking I/O. If no data is available, then it flushes its in-core data structures. The default number of seconds to time out before flushing is 300. This timeout may be changed by using the `-t` flag.

To limit the number of incoming NNTP connections, use the `-i` flag. A value of 0 suppresses this check.

To limit the number of files that are kept open for outgoing file feeds, use the `-o` flag. The default is the number of available descriptors minus some reserved for internal use.

To limit the size of an article, use the `-l` flag. If this flag is used, then any article bigger than `size` bytes is rejected. The default is no checking, which can also be obtained by using a value of 0.

`innd` rejects articles that are too old. Although this behavior can be controlled by the history database, occasionally a site dumps a batch of very old news back onto the network. Use the `-c` flag to specify a cutoff. For example, `-c21` rejects any articles that were posted more than 21 days ago. A value of 0 suppresses this check.

`innd` usually puts itself into the background, sets its standard output and error to log files, and disassociates itself from the terminal. Using the `-d` flag instructs the server to not do this, whereas using the `-f` flag just leaves the server running the foreground. The logs are usually buffered; use the `-u` flag to have them unbuffered.

To start the server in a paused or throttled state (see `ctlinnd(8)`) use the `-m` flag to set the initial running mode. The argument should start with a single letter `g`, `p`, or `t` to emulate the `go`, `pause`, or `throttle` commands.

If the `-r` flag is used, the server rennumbers the active file as if a `renumber` command were sent.

If the `-s` flag is used, then `innd` does not do any work but instead just checks the syntax of the `news-feeds` file. It exits with an error status if there are any errors; the actual errors are reported in `syslog(3)`.

If `innd` gets an `NOSPC` error (see `intro(2)`) while trying to write the active file, an article file, or the history database, it sends itself a `throttle` command. This also happens if it gets too many I/O errors while writing to any files.

Any subprocesses spawned by the server get a `nice(2)` value of `10`.

The `-n` flag specifies whether pausing or throttling the server should also disable future news-reading processes. A value of `y` makes news readers act as the server, a value of `n` allows news reading even when the server is not running.

If the `-s` flag is used, then `innd` runs in `slave` mode. When running as a slave, the server only accepts articles from the specified host, which must use the `xreplic` protocol extension. Note that either the host must appear in the `hosts.nntp` file or the server must be started with the `-a` flag.

By default, if a host is not mentioned in the `hosts.nntp` file, then the connection is handed off to `nnrpd`. If the `-a` flag is used, then any host can connect and transfer articles.

If the `-x` flag is used, then a `Xref` header is added to all articles even if they are not cross-posted.

`inndstart` is a small front-end program that opens the NNTP port, sets its user ID and group ID to the news maintainer, and then executes `innd` with the `-p` flag and a minimal secure environment. This is a small, easily understood front-end program that can be used if a site does not want to run `innd` with root privileges.

CONTROL MESSAGES

Arriving articles that have a `Control` header or have a `Subject` header that starts with the five characters `cmsg` are called control messages. Except for the cancel message, these messages are implemented by external programs in the `/news/bin/control` directory. (Cancel messages update the history database, so they must be handled internally; the cost of synching, locking, and then unlocking is too high, given the number of cancel messages that are received.)

When a control message arrives, the first word of the text is converted to lowercase and used as the name of the program to execute; if the named program does not exist, then a program named `default` is executed.

All control programs are invoked with four parameters. The first is the address of the person who posted the message; this is taken from the `Sender` header. If that header is empty, then it is taken from the `From` header. The second parameter is the address to send replies to; this is taken from the `Reply-To` header. If that header is empty, then the poster's address is used. The third parameter is a name under which the article is filed, relative to the news spool directory. The fourth parameter is the host that sent the article, as specified on the `Path` line.

The distribution of control message is also different from those of standard articles.

Control messages are usually filed in the newsgroup named `control`. They can be filed in subgroups, however, based on the control message command. For example, a `newgroup` message is filed in `control.newgroup` if that group exists, otherwise it will be filed in `control`.

Sites may explicitly have the "control" newsgroup in their subscription list, although it is usually best to exclude it. If a control message is posted to a group whose name ends with the four characters `.ctl`, then the suffix is stripped off and what is left is used as the group name. For example, a cancel message posted to `news.admin.ctl` will be sent to all sites that subscribe to `control` or `news.admin.newgroup` and `rmgroup` messages receive additional special treatment. If the message is approved and posted to the name of the group being created or removed, then the message is sent to all sites whose subscription patterns would cause them to receive articles posted in that group.

If an article is posted to a newsgroup that starts with the three letters `to.`, it gets special treatment if the newsgroup does not exist in the active file. The article is filed into the newsgroup `to` and it is sent to the first site named after the prefix. For example, a posting to `to.uunet` is filed in `to` and sent to the site `uunet`.

PROTOCOL DIFFERENCES

`innd` implements the NNTP commands defined in RFC 977 with the following differences:

- The `list` may be followed by an optional `active`, `active.times`, or `newsgroups` argument. This common extension is not fully supported; see `nnrpd(8)`.
- The `authinfo user` and `authinfo pass` commands are implemented. These are based on the reference UNIX implementation; no other documentation is available.
- A new command, `mode reader`, is provided. This command causes the server to pass the connection on to `nnrpd`. The command `mode query` is intended for future use and is currently treated the same way.
- A new command, `xreplic news.group:art[,news.group:art]`, is provided. This is similar to the `ihave` command (the same reply codes are used) except for the data that follows the command word. The data consists of entries separated by a single comma. Each entry consists of a newsgroup name, a colon, and an article number. Once processed, the article is filed in the newsgroup and article numbers specified in the command.
- A new command, `xpath messageid`, is provided. The server responds with a 223 response and a space-separated list of filenames where the article was filed.
- The only other commands implemented are `head`, `help`, `ihave`, `quit`, and `stat`.

HEADER MODIFICATIONS

`innd` modifies as few article headers as possible, although it could be better in this area.

The following headers, if present, are removed:

```
Date-Received
Posted
Posting-Version
Received
Relay-Version
```

Empty headers and headers that consist of nothing but whitespace are also dropped.

The local site's name and an exclamation point are prepended to the Path header.

The Xref header is removed. If the article is cross-posted, a new header is generated.

The Lines header is added if it is missing.

`innd` does not rewrite incorrect headers. For example, it does not replace an incorrect Lines header but rejects the article.

LOGGING

`innd` reports all incoming articles in its log file. This is a text file with a variable number of space-separated fields in one of the following formats:

```
mon dd hh:mm:ss.mmm + feed <Message-ID>site...
mon dd hh:mm:ss.mmm j feed <Message-ID> site...
mon dd hh:mm:ss.mmm c feed <Message-ID> site...
mon dd hh:mm:ss.mmm - feed <Message-ID> reason...
```

The first three fields are the date and time to millisecond resolution. The fifth field is the site that sent the article (based on the Path header), and the sixth field is the article's Message-ID; they will contain a question mark if the information is not available.

The fourth field indicates whether the article was accepted. If it is a plus sign, the article was accepted. If it is the letter `j`, the article was accepted, but all of newsgroups have a `j` in their active field, so the article was filed into the "junk" newsgroup. If the fourth field is the letter `c`, a cancel message was accepted before the original article arrived. In all three cases, the article has been accepted and the `site...` field contains the space-separated list of sites to which the article is sent.

If the fourth field is a minus sign, the article was rejected. The reasons for rejection include

```
%s header too long
%s wants to cancel <%s> by %s
Article exceeds local limit of %s bytes
Article posted in the future—%s
```

Bad %s header
 Can't write history
 Duplicate
 Duplicate %s header
 EOF in headers
 Linecount %s != %s +- %s
 Missing %s header
 No body
 No colon-space in %s header
 No space
 Space before colon in %s header
 Too old—%s
 Unapproved for %s
 Unwanted newsgroup %s
 Unwanted distribution %s
 Whitespace in “Newsgroups” header—%s

Where %s, above, is replaced by more specific information.

Note that if an article is accepted and none of the newsgroups are valid, it is logged with both two lines, a `j` line and a minus sign line.

`innnd` also makes extensive reports through `syslog`. The first word of the log message is the name of the site if the entry is site-specific (such as a `connected` message). The first word is `ME` if the message relates to the server itself, such as when a read error occurs.

If the second word is the four letters `cant`, an error is being reported. In this case, the next two words generally name the system call or library routine that failed and the object upon which the action was performed. The rest of the line might contain other information.

In other cases, the second word attempts to summarize what change has been made, and the rest of the line gives more specific information. The word `internal` generally indicates an internal logic error.

innxmit

`innxmit`—Send Usenet articles to a remote NNTP server.

SYNOPSIS

```
innxmit [ -A alt_spool ][-a ][-d ][-M ][-r ][-t timeout ]
[-T timeout ][-p ][-S ] host file
```

DESCRIPTION

`innxmit` connects to the NNTP server at the specified host and sends it the articles specified in the batchfile named `file`. It is usually invoked by a script run out of `cron(8)` that uses `shlock(1)` to lock the hostname, followed by `actlinnd(8)` command to flush the batchfile.

`innxmit` usually blocks until the connection is made. To specify a timeout on how long to try to make the connection, use the `-t` flag. To specify the total amount of time that should be allowed for article transfers, use the `-T` flag. The default is to wait until an I/O error occurs or all the articles have been transferred. If the `-T` flag is used, the time is checked just before an article is started; it does not abort a transfer that is in progress. Both values are measured in seconds.

If the file is not an absolute pathname, it is taken relative to the `/news/spool/out.going` directory. It is usually written by specifying the `Wnm` flags in the `newsfeeds(5)` file. Each line in the batchfile should be in one of the following formats:

```
filename Message-ID
filename
```

The `filename` field names the article to be sent. If it is not an absolute pathname, it is taken relative to the news spool directory, `/news/spool`. If the `Message-ID` field is not specified, it is obtained by scanning the article. The `filename` and `Message-Id` fields are separated by a space.

If a communication error such as a `write(2)` failure occurs, `innxmit` stops sending and rewrites the batchfile to contain the current article and any other unsent articles.

If the remote server sends an unexpected reply code, `innxmit` requeues the article and proceeds. Use the `-r` flag if the article should not be requeued.

Upon exit, `innxmit` reports transfer and CPU usage statistics via `syslog(3)`. If the `-v` flag is used, they are also printed on the standard output. If all articles were sent successfully, `innxmit` removes the batchfile; otherwise, it rewrites it to contain the list of unsent articles. If no articles were sent or rejected, the file is left untouched. This can cause the batchfile to grow excessively large if many articles have been expired and there are communication problems. To always rewrite the batchfile, use the `-a` flag. If the `-p` flag is given, then no connection is made and the batchfile is purged of entries that refer to files that no longer exist. This implies the `-a` flag.

If the `-s` flag is given, then `innxmit` offers articles to the specified host using the `xrepl` protocol extension described in `innd(8)`. To use this flag, the input file must contain the history data (commas are transliterated to spaces by the server). For this flag to be used, the input must contain the necessary history entries. This is usually done by setting up a `Wnr` entry in the `newsfeeds` file.

Use the `-d` flag to print debugging information on standard error. This shows the protocol transactions between `innxmit` and the NNTP server on the remote host.

If the `-M` flag is used, `innxmit` scans an article's headers before sending it. If the article appears to be a MIME article that is not in seven-bit format, the article is sent in "quoted-printable" form.

The `-A` flag may be used to specify an alternate spool directory to use if the article is not found; this is usually an NFS-mounted spool directory of a master server with longer expiration times.

ipcs

`ipcs`—Provide information on ipc facilities.

SYNOPSIS

```
ipcs [ -asmq ] [ -tclup ]
ipcs [ -smq ] -i id
ipcs -h
```

DESCRIPTION

`ipcs` provides information on the ipc facilities for which the calling process has read access.The `-i` option allows a specific resource `id` to be specified. Only information on this `id` is printed.

Resources may be specified as follows:

<code>-m</code>	Shared memory segments
<code>-q</code>	Message queues
<code>-s</code>	Semaphore arrays
<code>-a</code>	All (this is the default)

The output format may be specified as follows:

<code>-t</code>	Time
<code>-p</code>	PID
<code>-c</code>	Creator
<code>-l</code>	Limits
<code>-u</code>	Summary

kbdrate

`kbdrate`—Reset the keyboard repeat rate and delay time.

SYNOPSIS

```
kbdrate [ -s ] [ -r rate ] [-d delay ]
```

DESCRIPTION

`kbdrate` is used to change the IBM keyboard repeat rate and delay time. The delay is the amount of time that a key must be pressed before it starts to repeat. Using `kbdrate` without any options resets the rate to 10.9 characters per second (cps) and the delay to 250 milliseconds (ms). These are the IBM defaults.

OPTIONS

- s Silent. No messages are printed.
- r *rate* Change the keyboard repeat rate to *rate* cps. The allowable range is from 2.0 to 30.0 cps. Only certain specific values are possible, and the program selects the nearest possible value to the one specified. The possible values are given, in characters per second, as follows: 2.0, 2.1, 2.3, 2.5, 2.7, 3.0, 3.3, 3.7, 4.0, 4.3, 4.6, 5.0, 5.5, 6.0, 6.7, 7.5, 8.0, 8.6, 9.2, 10.0, 10.9, 12.0, 13.3, 15.0, 16.0, 17.1, 18.5, 20.0, 21.8, 24.0, 26.7, 30.0.
- d *delay* Change the delay to *delay* milliseconds. The allowable range is from 250 to 1000 ms, but the only possible values (based on hardware restrictions) are 250 ms, 500 ms, 750 ms, and 1000 ms.

BUGS

Not all keyboards support all rates.

Not all keyboards have the rates mapped in the same way.

Setting the repeat rate on the Gateway AnyKey keyboard does not work. If someone with a Gateway figures out how to program the keyboard, please send mail to faith@cs.unc.edu.

klogd

`klogd`—Kernel log daemon.

SYNOPSIS

```
klogd -c [n] -d -f [fname] -os
```

DESCRIPTION

`klogd` is a system daemon that intercepts and logs Linux kernel messages.

OPTIONS

- c Sets the default log level of console messages to *[n]*.
- d Enables debugging mode. This will generate a lot of output to `stderr`.
- f Logs messages to the specified filename rather than to the `syslog` facility.
- o Execute in one-shot mode. This causes `klogd` to read and log all the messages that are found in the kernel message buffers. After a single read and log cycle, the daemon exits.
- s Force `klogd` to use the system call interface to the kernel message buffers.

OVERVIEW

The functionality of `klogd` has been typically incorporated into other versions of `syslogd`, but this seems to be a poor place for it. In the modern Linux kernel, a number of kernel messaging issues such as sourcing and prioritization must be addressed. Incorporating kernel logging into a separate process appears to offer a cleaner separation of services.

In Linux, there are two potential sources of kernel log information: the `/proc` filesystem and the `syscall` (`sys_syslog`) interface, although ultimately they are one and the same. `klogd` is designed to choose whichever source of information is the most appropriate. It does this by first checking for the presence of a mounted `/proc` filesystem. If this is found, the `/proc/kmsg` file is used as the source of kernel log information. If the `proc` filesystem is not mounted, `klogd` uses a system call to obtain kernel messages. The command-line switch (`-s`) can be used to force `klogd` to use the system call interface as its messaging source.

If kernel messages are directed through the `syslogd` daemon, the `klogd` daemon, as of version 1.1, has the ability to properly prioritize kernel messages. Prioritization of the kernel messages was added at approximately the `pl13` level of the kernel. The raw kernel messages are of the form:

```
<[0-7]>Something said by the kernel .
```

The priority of the kernel message is encoded as a single numeric digit enclosed inside the `<>` pair. The definitions of these values is given in the kernel include file `kernel.h`. When a message is received from the kernel, the `klogd` daemon reads this priority level and assigns the appropriate priority level to the `syslog` message. If file output (`-f`) is used, the prioritization sequence is left prepended to the kernel message.

The `klogd` daemon also allows the ability to alter the presentation of kernel messages to the system console. Consequent with the prioritization of kernel messages was the inclusion of default messaging levels for the kernel. In a stock kernel, the default console log level is set to 7. Any messages with a priority level numerically lower than 7 (higher priority) appear on the console.

Messages of priority level 7 are considered to be debug messages and do not appear on the console. Many administrators, particularly in a multi-user environment, prefer that all kernel messages be handled by `klogd` and either directed to a file or to the `syslogd` daemon. This prevents nuisance messages such as line printer out of paper or disk change detected from cluttering the console.

By default, the `klogd` daemon executes a system call to inhibit all kernel messages (except for panics) from being displayed on the console. The `-c` switch can be used to alter this behavior. The argument given to the `-c` switch specifies the priority level of messages that are directed to the console. Note that messages of a priority value lower than the indicated number are directed to the console.

For example, to have the kernel display all messages with a priority level of 3 (`KERN_ERR`) or more severe, the following command is executed:

```
klogd -c 4
```

The definitions of the numeric values for kernel messages are given in the file `kernel.h`, which can be found in the `/usr/include/linux` directory if the kernel sources are installed. These values parallel the `syslog` priority values, which are defined in the file `syslog.h`, found in the `/usr/include/sys` subdirectory.

The `klogd` daemon can also be used in a one-shot mode for reading the kernel message buffers. One-shot mode is selected by specifying the `-o` switch on the command line. Output is directed to either the `syslogd` daemon or to an alternate file specified by the `-f` switch.

For example, to read all the kernel messages after a system boot and record them in a file called `krrn1.msg`, the following command is given:

```
klogd -o -f ./krrn1.msg
```

SIGNAL HANDLING

The `klogd` daemon responds to six signals: `SIGHUP`, `SIGINT`, `SIGKILL`, `SIGTERM`, `SIGTSTP`, and `SIGCONT`. The `SIGINT`, `SIGKILL`, `SIGTERM`, and `SIGHUP` signals cause the daemon to close its kernel log sources and terminate gracefully.

The SIGTSTP and SIGCONT signals are used to start and stop kernel logging. Upon receipt of a SIGTSTP signal, the daemon closes its log sources and spins in an idle loop. Subsequent receipt of a SIGCONT signal causes the daemon to go through its initialization sequence and rechoose an input source. Using SIGSTOP and SIGCONT in combination, the kernel log input can be rechosen without stopping and restarting the daemon. For example, if the /proc filesystem is to be unmounted, the following command sequence should be used:

```
# kill -TSTP pid
# umount /proc
# kill -CONT pid
```

Notations will be made in the system logs with LOG INFO priority documenting the start/stop of logging.

FILES

/proc/kmsg

BUGS

Probably numerous. Well-formed context diffs appreciated.

lpc

lpc—Line printer control program.

SYNOPSIS

```
lpc [command [argument ...]]
```

DESCRIPTION

lpc is used by the system administrator to control the operation of the line printer system. For each line printer configured in /etc/printcap, lpc may be used to

- Disable or enable a printer
- Disable or enable a printer's spooling queue
- Rearrange the order of jobs in a spooling queue
- Find the status of printers and their associated spooling queues and printer daemons

Without any arguments, lpc prompts for commands from the standard input. If arguments are supplied, lpc interprets the first argument as a command and the remaining arguments as parameters to the command. The standard input may be redirected, causing lpc to read commands from file. Commands may be abbreviated; the following is the list of recognized commands:

```
? [ command ... ]help [ command ... ]
```

Print a short description of each command specified in the argument list or, if no arguments are given, a list of the recognized commands.

```
lpc abort No all - printer
```

Terminate an active spooling daemon on the local host immediately and then disable printing (preventing new daemons from being started by lpr) for the specified printers.

```
lpc clean No all - printer
```

Remove any temporary files, data files, and control files that cannot be printed (that is, they do not form a complete printer job) from the specified printer queues on the local machine.

```
lpc disable No all - printer
```

Turn the specified printer queues off. This prevents new printer jobs from being entered into the queue by lpr.

<code>lc down No all - printer message ...</code>	Turn the specified printer queue off, disable printing, and put <code>message</code> in the printer status file. The message doesn't need to be quoted; the remaining arguments are treated like <code>echo(1)</code> . This is usually used to take a printer down and let others know why <code>lpq(1)</code> indicates the printer is down and print the status message.
<code>enable No all -- printer</code>	Enable spooling on the local queue for the listed printers. This allows <code>lpr(1)</code> to put new jobs in the spool queue.
<code>exit, quit</code>	Exit from <code>lpc</code> .
<code>restart all - printer</code>	Attempt to start a new printer daemon. This is useful when some abnormal condition causes the daemon to die unexpectedly leaving jobs in the queue. <code>lpq</code> reports that there is no daemon present when this condition occurs. If the user is the super-user, try to abort the current daemon first (that is, kill and restart a stuck daemon).
<code>start all - printer</code>	Enable printing and start a spooling daemon for the listed printers.
<code>status No all - printer</code>	Display the status of daemons and queues on the local machine.
<code>stop all - printer</code>	Stop a spooling daemon after the current job completes and disable printing.
<code>topq printer [jobnum ...] [user ...]</code>	Place the jobs in the order listed at the top of the printer queue.
<code>up all - printer</code>	Enable everything and start a new printer daemon. Undoes the effects of <code>down</code> .

FILES

<code>/etc/printcap</code>	printer description file
<code>/var/spool/*</code>	spool directories
<code>/var/spool/*/lock</code>	lock file for queue control

SEE ALSO

`lpd(8)`, `lpr(1)`, `lpq(1)`, `lprm(1)`, `printcap(5)`

DIAGNOSTICS

<code>?Ambiguous command</code>	Abbreviation matches more than one command.
<code>?Invalid command</code>	No match was found.
<code>?Privileged command</code>	Command can be executed by root only.

HISTORY

The `lpc` command appeared in BSD 4.2.

BSD 4.2, 16 March 1991

lpd

`lpd`—Line printer spooler daemon.

SYNOPSIS

```
lpd [-l] [port#]
```

DESCRIPTION

`lpd` is the line printer daemon (spool area handler) and is usually invoked at boot time from the `rc(8)` file. It makes a single pass through the `printcap(5)` file to find out about the existing printers and prints any files left after a crash. It then uses the system calls `listen(2)` and `accept(2)` to receive requests to print files in the queue, transfer files to the spooling area, display

the queue, or remove jobs from the queue. In each case, it forks a child to handle the request so the parent can continue to listen for more requests.

Available options:

-l	The <code>-l</code> flag causes <code>lpd</code> to log valid requests received from the network. This can be useful for debugging purposes.
port#	The Internet port number used to rendezvous with other processes is usually obtained with <code>getservbyname(3)</code> but can be changed with the <code>port#</code> argument.

Access control is provided by two means. First, all requests must come from one of the machines listed in the file `/etc/hosts.equiv` or `/etc/hosts.lpd`. Second, if the `rs` capability is specified in the `printcap` entry for the printer being accessed, `lpr` requests are only honored for those users with accounts on the machine with the printer.

The file `minfree` in each spool directory contains the number of disk blocks to leave free so that the line printer queue won't completely fill the disk. The `minfree` file can be edited with your favorite text editor.

The daemon begins processing files after it has successfully set the lock for exclusive access (described later) and scans the spool directory for files beginning with `cf`. Lines in each `cf` file specify files to be printed or non-printing actions to be performed. Each such line begins with a key character to specify what to do with the remainder of the line:

J	Job name. String to be used for the job name on the burst page.
C	Classification. String to be used for the classification line on the burst page.
L	Literal. The line contains identification info from the password file and causes the banner page to be printed.
T	Title. String to be used as the title for <code>pr(1)</code> .
H	Host name. Name of the machine where <code>lpr</code> was invoked.
P	Person. Login name of the person who invoked <code>lpr</code> . This is used to verify ownership by <code>lprm</code> .
M	Send mail to the specified user when the current print job completes.
f	Formatted file. Name of a file to print which is already formatted.
l	Like <code>f</code> but passes control characters and does not make page breaks.
p	Name of a file to print using <code>pr(1)</code> as a filter.
t	Troff file. The file contains <code>troff(1)</code> output (cat phototypesetter commands).
n	Ditroff file. The file contains device independent <code>troff</code> output.
r	DVI file. The file contains Tex <code>l</code> output DVI format from Stanford.
g	Graph file. The file contains data produced by <code>p1ot(3)</code> .
c	Cifplot file. The file contains data produced by <code>cifp1ot</code> .
v	The file contains a raster image.
r	The file contains text data with FORTRAN carriage control characters.
1	Troff font R. Name of the font file to use instead of the default.
2	Troff font I. Name of the font file to use instead of the default.
3	Troff font B. Name of the font file to use instead of the default.
4	Troff font S. Name of the font file to use instead of the default.
W	Width. Changes the page width (in characters) used by <code>pr(1)</code> and the text filters.
I	Indent. The number of characters to indent the output by (in ASCII).
U	Unlink. Name of file to remove upon completion of printing.
N	Filename. The name of the file that is being printed or a blank for the standard input (when <code>lpr</code> is invoked in a pipeline).

If a file cannot be opened, a message is logged via `syslog(3)` using the `LOG_LPR` facility. `lpd` tries up to 20 times to reopen a file it expects to be there, after which it skips the file to be printed.

`lpd` uses `flock(2)` to provide exclusive access to the lock file and to prevent multiple daemons from becoming active simultaneously. If the daemon should be killed or die unexpectedly, the lock file need not be removed. The lock file is kept in a readable ASCII form and contains two lines. The first is the process ID of the daemon and the second is the control filename of the current job being printed. The second line is updated to reflect the current status of `lpd` for the programs `lpq(1)` and `lprm(1)`.

FILES

<code>/etc/printcap</code>	Printer description file
<code>/var/spool/*</code>	Spool directories
<code>/var/spool/*/minfree</code>	Minimum free space to leave
<code>/dev/lp*</code>	Line printer devices
<code>/dev/printer</code>	Socket for local requests
<code>/etc/hosts.equiv</code>	Lists machine names allowed printer access
<code>/etc/hosts.lpd</code>	Lists machine names allowed printer access but not under same administrative control

SEE ALSO

`lpc(8)`, `pac(1)`, `lpr(1)`, `lpq(1)`, `lprm(1)`, `syslog(3)`, `printcap(5)`

4.2 BSD Line Printer Spooler Manual

HISTORY

An `lpd` daemon appeared in Version 6, AT&T UNIX.

BSD 4.2, 16 March 1991

MAKEDEV

MAKEDEV—Creates and maintains filesystem device entries.

SYNOPSIS

```
MAKEDEV [ -vcdnhV ] device or device-group names
```

DESCRIPTION

MAKEDEV is used to maintain the special filesystem entries found in `/dev`. It creates, or optionally removes, one or more device entries. The names and device numbers are defined in the `devinfo` file (`q.v.`); site-specific configuration is found in the file `MAKEDEV.cfg`. **MAKEDEV** itself has no knowledge of device information.

OPTIONS

<code>-v</code>	Verbose mode; print out exactly what's being done.
<code>-c</code>	Create; create the specified devices (default).
<code>-d</code>	Delete; remove the specified devices instead of creating them.
<code>-n</code>	Do nothing; only print what would be done. Implies <code>-v</code> as well.
<code>-h</code>	Print a usage message.
<code>-V</code>	Print the version string.

The following targets are special:

<code>update</code>	Run MAKEDEV in update mode. This reads the list of devices currently available from <code>/proc/devices</code> and updates all entries in <code>/dev</code> to match the device numbers found there.
---------------------	---

local Run MAKEDEV to create local devices. This option is obsolete and just prints a warning message. Use `devinfo.local` and `madev.cfg` to achieve the same results.

FILES

<code>/etc/devinfo</code>	Device information
<code>/usr/local/etc/devinfo.local</code>	Local device information
<code>/etc/devinfo.local</code>	Alternate location for local device information
<code>/etc/makedev.cfg</code>	Configuration file
<code>MAKEDEV.cache</code>	Cached data for update
<code>/proc/devices</code>	The kernel's list of current devices

AUTHOR

David A. Holland (`dholland@husc.harvard.edu`). Based on the older MAKEDEV shell script written by Nick Holloway. Additional ideas were contributed by Rik Faith.

NOTES

The LALR(1) parser generator used to build `madev.c` from `madev.syn` is a commercial product. You won't be able to do a complete rebuild unless you have it.

`devinfo(5)`, `madev.cfg(5)`

Version 1.5, March 1995

MAKEDEV

MAKEDEV—Creates devices.

SYNOPSIS

```
cd dev; ./MAKEDEV -V
cd dev; ./MAKEDEV [ -n ] [ -v ] update
cd dev; ./MAKEDEV [ -n ] [ -v ] [ -d ] device ...
```

DESCRIPTION

MAKEDEV is a script that creates the devices in `/dev` used to interface with drivers in the kernel.

Note that programs giving the error `ENOENT: No such file or directory` usually means that the device file is missing, whereas `ENODEV: No such device` usually means the kernel does not have the driver configured or loaded.

OPTIONS

<code>-v</code>	Print out version (actually RCS version information) and exit.
<code>-n</code>	Do not actually update the devices; just print the actions that would be performed.
<code>-d</code>	Delete the devices. The main use for this flag is by MAKEDEV itself.
<code>-v</code>	Be verbose. Print out the actions as they are performed. This is the same output as produced by <code>-n</code> .

CUSTOMIZATION

Because there is currently no standardization in what names are used for system users and groups, it is possible that you might need to modify MAKEDEV to reflect your site's settings. Near the top of the file is a mapping from device type to user, group, and permissions. (For example, all CD-ROM devices are set from the `$cdrom` variable.) If you want to change the defaults, this is the section to edit.

DEVICES

General Options

update	This only works on kernels that have <code>/proc/interrupts</code> (introduced during 1.1.x). This file is scanned to see what devices are currently configured into the kernel, and this is compared with the previous settings stored in the file called <code>DEVICES</code> . Devices that are new since then or have a different major number are created, and those that are no longer configured are deleted.
generic	Create a generic subset of devices. This is the standard devices, plus floppy drives, various hard drives, pseudo-terminals, console devices, basic serial devices, busmice, and printer ports.
%std	Standard devices. These are <code>mem</code> , access to physical memory; <code>kmem</code> , access to kernel virtual memory; <code>null</code> , null device (infinite sink); <code>port</code> , access to I/O ports; <code>zero</code> , null byte source (infinite source); <code>core</code> , symlink to <code>/proc/kcore</code> (for kernel debugging); <code>full</code> , always returns <code>ENOSPACE</code> on write; <code>ram</code> , <code>ramdisk</code> ; <code>tty</code> , to access the controlling <code>tty</code> of a process.
local	This simply runs <code>MAKEDEV.local</code> . This is a script that can create any local devices.

Virtual Terminals

console	This creates the devices associated with the console. This is the virtual terminals <code>ttyx</code> , where <code>x</code> can be from <code>0</code> through <code>63</code> . The device <code>tty0</code> is the currently active vt and is also known as <code>console</code> . For each vt, there are two devices, <code>vcsx</code> and <code>vcsax</code> , which are used to generate screen-dumps of the vt (the <code>vcsx</code> is just the text and <code>vcsax</code> includes the attributes).
---------	---

Serial Devices

<code>ttyS{0..63}</code>	Serial ports and corresponding dial-out device. For device <code>ttySx</code> , there is also the device <code>cuax</code> , which is used to dial out with. This can avoid the need for cooperative locks in simple situations.
cyclades	Dial-in and dial-out devices for the cyclades intelligent I/O serial card. The dial in device is <code>ttyCx</code> and the corresponding dial-out device is <code>cubx</code> . By default, devices for 7 lines are created, but this can be changed to 15 by removing the comment.

Pseudo Terminals

<code>pty[p-s]</code>	Each possible argument will create a bank of 16 master and slave pairs. The current kernel (1.2) is limited to 64 such pairs. The master pseudo-terminals are <code>pty[p-s][0-9a-f]</code> and the slaves are <code>tty[p-s][0-9a-f]</code> .
-----------------------	--

Parallel Ports

lp	Standard parallel ports. The devices are created <code>lp0</code> , <code>lp1</code> , and <code>lp2</code> . These correspond to ports at <code>0x3bc</code> , <code>0x378</code> , and <code>0x278</code> . Hence, on some machines, the first printer port may actually be <code>lp1</code> .
par	Alternative to <code>lp</code> . Ports are named <code>parx</code> instead of <code>lpx</code> .

Bus Mice

busmice	The various bus mice devices. This creates the following devices: <code>logimouse</code> (Logitech bus mouse), <code>psmouse</code> (PS/2-style mouse), <code>msmouse</code> (Microsoft Inport bus mouse), <code>atimouse</code> (ATI XL bus mouse) and <code>jmouse</code> (J-mouse).
---------	--

Joystick Devices

js	Joystick. Creates <code>js0</code> and <code>js1</code> .
----	---

Disk Devices

<code>fd[0-7]</code>	Floppy disk devices. The device <code>fdx</code> is the device that autodetects the format, and the additional devices are fixed format (whose size is indicated in the name). The other devices are named as
----------------------	---

	<p><code>fdxLn</code>. The single letter <code>L</code> identifies the type of floppy disk (<code>d</code> = 5.25" DD, <code>h</code> = 5.25" HD, <code>D</code> = 3.5" DD, <code>H</code> = 3.5" HD, <code>E</code> = 3.5" ED). The number <code>n</code> represents the capacity of that format in KB. Thus the standard formats are <code>fdxd360</code>, <code>fdxh1200</code>, <code>fdxD720</code>, <code>fdxH1440</code>, and <code>fdxE2880</code>.</p> <p>For more information, see Alain Knaff's <code>fdutils</code> pack-age.</p> <p>Devices <code>fd0*</code> through <code>fd3*</code> are floppy disks on the first controller, and devices <code>fd4*</code> through <code>fd7*</code> are floppy disks on the second controller.</p>
<code>hd[a-d]</code>	<p>AT hard disks. The device <code>hdX</code> provides access to the whole disk, with the partitions being <code>hdX[0-20]</code>. The four primary partitions are <code>hdX1</code> through <code>hdX4</code>, with the logical partitions being numbered from <code>hdX5</code> through <code>hdX20</code>. (A primary partition can be made into an extended partition, which can hold four logical partitions). By default, only the devices for four logical partitions are made. The others can be made by uncommenting them.</p> <p>Drives <code>hda</code> and <code>hdb</code> are the two on the first controller. If using the new IDE driver (rather than the old HD driver), then <code>hdc</code> and <code>hdd</code> are the two drives on the secondary controller. These devices can also be used to access IDE CD-ROMs if using the new IDE driver.</p>
<code>xd[a-d]</code>	XT hard disks. Partitions are the same as IDE disks.
<code>sd[a-h]</code>	SCSI hard disks. The partitions are similar to the IDE disks, but there is a limit of 11 logical partitions (<code>sdX5</code> through <code>sdX15</code>). This is to allow 8 SCSI disks.
<code>loop</code>	Loopback disk devices. These allow you to use a regular file as a block device. This means that images of filesystems can be mounted and used as normal. This creates 8 devices <code>loop0</code> through <code>loop7</code> .

Tape Devices

<code>st[0-7]</code>	SCSI tapes. This creates the rewinding tape device <code>stX</code> and the non-rewinding tape device <code>nstX</code> .
<code>qic</code>	QIC-80 tapes. The devices created are <code>rmt8</code> , <code>rmt16</code> , <code>tape-d</code> , and <code>tape-reset</code> .
<code>ftape</code>	Floppy driver tapes (QIC-117). There are four methods of access depending on the floppy tape drive. For each of the access methods 0, 1, 2, and 3, the devices <code>rftX</code> (rewinding) and <code>nrftX</code> (non-rewinding) are created. For compatibility, devices <code>ftape</code> and <code>nftape</code> are symlinks to <code>rft0</code> and <code>nrft0</code> .

CD-ROM Devices

<code>scd[0-7]</code>	SCSI CD players.
<code>sonycd</code>	Sony CDU-31A CD player.
<code>mcid</code>	Mitsumi CD player.
<code>cdu535</code>	Sony CDU-535 CD player.
<code>lmscd</code>	LMS/Philips CD player.
<code>sbpcd{,1,2,3}</code>	SoundBlaster CD player. The kernel is capable of supporting 16 CD-ROMs, each of which is accessed as <code>sbpcd[0-9a-f]</code> . These are assigned in groups of four to each controller. <code>sbpcd</code> is a symlink to <code>sbpcd0</code> .

Scanner

<code>logiscan</code>	Logitech ScanMan32 and ScanMan 256.
<code>m105scan</code>	Mustek M105 Handscanner.
<code>ac4096</code>	A4Tek Color Handscanner.

Audio

<code>audio</code>	This creates the audio devices used by the sound driver. These include <code>mixer</code> , <code>sequencer</code> , <code>dsp</code> , and <code>audio</code> .
<code>pcaudio</code>	Devices for the PC Speaker sound driver. These are <code>pcmixer</code> , <code>pxsp</code> , and <code>pcaudio</code> .

Miscellaneous

sg	Generic SCSI devices. The devices created <code>aresg0</code> through <code>sg7</code> . These allow arbitrary commands to be sent to any SCSI device. This allows for querying information about the device or controlling SCSI devices that are not one of disk, tape, or CD-ROM (for example, a scanner or writable CD-ROM).
fd	To allow an arbitrary program to be fed input from file descriptor <code>x</code> , use <code>/dev/fd/x</code> as the filename. This also creates <code>BR/dev/stdin</code> , <code>BR/dev/stdout</code> , and <code>BR/dev/stderr</code> . (Note that these are just symlinks into <code>/proc/self/fd</code> .)
ibcs2	Devices (and symlinks) needed by the IBCS2 emulation.
apm	Devices for power management.
dcf	Driver for DCF-77 radio clock.
helloworld	Kernel modules demonstration device. See the modules source.
Network devices	Linux used to have devices in <code>/dev</code> for controlling network devices, but that is no longer the case. To see what network devices are known by the kernel, look at <code>/proc/net/dev</code> .

mke2fs

`mke2fs`—Create a Linux second extended filesystem.

SYNOPSIS

```
mke2fs [ -c | -l filename ] [ -b block-size ] [ -f fragment-size ]
[ -i bytes-per-inode ] [ -m reserved-blocks-percentage ] [ -q ] [-v ] [-S ]
device [ blocks-count ]
```

DESCRIPTION

`mke2fs` is used to create a Linux second extended filesystem on a device (usually a disk partition). `device` is the special file corresponding to the device (such as `/dev/hdXX`). `blocks-count` is the number of blocks on the device. If omitted, `mke2fs` automatically figures the filesystem size.

OPTIONS

<code>-b block-size</code>	Specify the size of blocks in bytes.
<code>-c</code>	Check the device for bad blocks before creating the filesystem using a fast read-only test.
<code>-f fragment-size</code>	Specify the size of fragments in bytes.
<code>-i bytes-per-inode</code>	Specify the bytes/inode ratio. <code>mke2fs</code> creates an inode for every <code>bytes-per-inode</code> bytes of space on the disk. This value defaults to 4096 bytes. <code>bytes-per-inode</code> must be at least 1024.
<code>-l filename</code>	Read the bad blocks list from <code>filename</code> .
<code>-m reserved-blocks-percentage</code>	Specify the percentage of reserved blocks for the super-user. This value defaults to 5 percent.
<code>-q</code>	Quiet execution. Useful if <code>mke2fs</code> is run in a script.
<code>-v</code>	Verbose execution.

-s Write superblock and group descriptors only. This is useful if all the superblock and backup superblocks are corrupted and a last-ditch recovery method is desired. It causes `mke2fs` to reinitialize the superblock and group descriptors while not touching the inode table and the block and inode bitmaps. The `e2fsck` program should be run immediately after this option is used, and there is no guarantee that any data will be salvageable.

AUTHOR

This version of `mke2fs` has been written by Theodore T'so (`tytso@mit.edu`).

BUGS

`mke2fs` accepts the `-f` option but currently ignores it because the second extended filesystem does not support fragments yet. There may be some other bugs. Please report them to the author.

AVAILABILITY

`mke2fs` is available for anonymous FTP from `ftp.ibp.fr` and `tsx-11.mit.edu` in `/pub/linux/packages/ext2fs`.

Version 0.5b, November 1994

mkfs

`mkfs`—Build a Linux filesystem.

SYNOPSIS

```
mkfs [ -V ] [-t fstype ] [fs-options ] filesys [ blocks ]
```

DESCRIPTION

`mkfs` is used to build a Linux filesystem on a device, usually a hard disk partition. `filesys` is either the device name (such as `/dev/hda1`, `/dev/sdb2`) or the mount point (such as `/`, `/usr`, `/home`) for the filesystem. `blocks` is the number of blocks to be used for the filesystem.

The exit code returned by `mkfs` is 0 on success and 1 on failure.

In actuality, `mkfs` is simply a front end for the various filesystem builders (`mkfs.fstype`) available under Linux. The filesystem-specific builder is searched for in `/etc/fs` first, then in `/etc`, and finally in the directories listed in the `PATH` environment variable. Please see the filesystem-specific builder manual pages for further details.

OPTIONS

-V	Produce verbose output, including all filesystem-specific commands that are executed. Specifying this option more than once inhibits execution of any filesystem-specific commands. This is really only useful for testing.
-tfstype	Specifies the type of filesystem to be built. If not specified, the type is deduced by searching for <code>filesys</code> in <code>/etc/fstab</code> and using the corresponding entry. If the type cannot be deduced, the default filesystem type (currently <code>minix</code>) is used.
fs-options	Filesystem-specific options to be passed to the real filesystem builder. Although not guaranteed, the following options are supported by most filesystem builders.
-c	Check the device for bad blocks before building the filesystem.
-lfilename	Read the bad blocks list from <code>filename</code> .
-v	Produce verbose output.

BUGS

All generic options must precede and not be combined with filesystem-specific options. Some filesystem-specific programs do not support the `-v` (verbose) option nor return meaningful exit codes. Also, some filesystem-specific programs do not automatically detect the device size and require the `blocks` parameter to be specified.

AUTHORS

David Engel (david@ods.com), Fred N. van Kempen (waltje@uwal.t.n1.mugnet.org), and Ron Sommeling (sommel@sci.kun.nl). The manual page was shamelessly adapted from Remy Card's version for the `ext2` filesystem.

mkfs

`mkfs`—Make a Linux MINIX filesystem.

SYNOPSIS

```
mkfs [ -c ] [ -n nlength ] [ -i inodecount ] device size-in-blocks
mkfs [ -l filename ] device size-in-blocks
```

DESCRIPTION

`mkfs` creates a Linux MINIX filesystem on a device (usually a disk partition).

The device is usually of the following form:

```
/dev/hda[1-8]
/dev/hdb[1-8]
/dev/sda[1-8]
/dev/sdb[1-8]
```

The `size-in-blocks` parameter is the desired size of the filesystem in blocks. This information can be determined from the `fdisk(8)` program. Only block counts strictly greater than 10 and strictly less than 65,536 are allowed.

OPTIONS

<code>-c</code>	Check the device for bad blocks before creating the filesystem. If any are found, the count is printed.
<code>-n nlength</code>	Specify the maximum length of filenames. No space is allowed between the <code>-n</code> and the <code>nlength</code> . Currently, the only allowable values are 14 and 30. 30 is the default.
<code>-i inodecount</code>	Specify the number of inodes for the filesystem.
<code>-l filename</code>	Read the bad blocks list from <code>filename</code> . The file has one bad block number per line. The count of bad blocks read is printed.

EXIT CODES

The exit code returned by `mkfs.minix` is one of the following:

0	No errors
8	Operational error
16	Usage or syntax error

mklost+found

mklost+found—Create a lost+found directory on a mounted Linux second extended filesystem.

SYNOPSIS

```
mklost+found
```

DESCRIPTION

mklost+found is used to create a lost+found directory in the current working directory on a Linux second extended filesystem. mklost+found pre-allocates disk blocks to the directory to make it usable by e2fsck.

OPTIONS

There are none.

AUTHOR

mklost+found was written by **Remy Card** (card@masi.ibp.fr), the developer and maintainer of the ext2 fs.

BUGS

There are none. :-)

AVAILABILITY

mklost+found is available for anonymous FTP from ftp.ibp.fr and tsx-11.mit.edu in /pub/linux/packages/ext2fs.

mkswap

mkswap—Set up a Linux swap area.

SYNOPSIS

```
mkswap [ -c ] device [size-in-blocks]
```

DESCRIPTION

mkswap sets up a Linux swap area on a device or in a file.

The device is usually of the following form:

```
/dev/hda[1-8]  
/dev/hdb[1-8]  
/dev/sda[1-8]  
/dev/sdb[1-8]
```

The `size-in-blocks` parameter is the desired size of the filesystem in blocks. This information is determined automatically by `mkswap` if it is omitted. Block counts are rounded down so that the total size is an integer multiple of the machine's page size. Only block counts in the range `MINCOUNT..MAXCOUNT` are allowed. If the block count exceeds the `MAXCOUNT`, it is truncated to that value and a warning message is issued.

The `MINCOUNT` and `MAXCOUNT` values for a swap area are

```
MINCOUNT = 10 * PAGE_SIZE / 1024
MAXCOUNT = (PAGE_SIZE-10)*8 *PAGE_SIZE / 1024
```

For example, on a machine with 4KB pages (such as `x86`), we get

```
MINCOUNT = 10 * 4096 / 1024 = 40
MAXCOUNT = (4096 - 10) * 8 * 4096 / 1024 = 130752
```

As each block is 1KB, the swap area in this example could have a size that is anywhere in the range from 40KB to 127.6875MB.

If you don't know the page size that your machine uses, you may be able to look it up with `cat /proc/cpuinfo`.

The reason for the limit on `MAXCOUNT` is that a single page is used to hold the swap bitmap at the start of the swap area, where each bit represents a single page. The reason for the `-10`, is that the signature is `SWAP-SPACE - 10` characters.

To set up a swap file, it is necessary to create that file before running `mkswap`. A sequence of commands similar to the following is reasonable for this purpose:

```
# dd if=/dev/zero of=swapfile bs=1024 count=8192
# mkswap swapfile 8192
# sync
# swapon swapfile
```

Note that a swap file must not contain any holes (so using `cp(1)` to create the file is not acceptable).

OPTIONS

`-c` Check the device for bad blocks before creating the filesystem. If any are found, the count is printed. This option is meant to be used for swap partitions only and should not be used for regular files! To make sure that regular files do not contain bad blocks, the partition that contains the regular file should have been created with `mkfs -c`.

Linux 1.0, 8 February 1995

mount, umount

`mount`, `umount`—Mount and dismount filesystems.

SYNOPSIS

```
mount [-afrwuvn] [-t vfstype]
mount [-frwuvn] [-o remount [...]] special | node
mount [-frwun] [-t vfstype] [-o options] special | node
umount [-an] [-t vfstype]
umount special | node
```

DESCRIPTION

The `mount` command calls the `mount(2)` system call to prepare and graft a special device onto the filesystem tree at the point node. If either `special` or `node` are not provided, the appropriate information is taken from the `fstab(5)` file. The special keyword `none` can be used instead of a path or node specification. This is useful when mounting the `proc` filesystem.

The system maintains a list of currently mounted filesystems. If no arguments are given to `mount`, this list is printed.

Options available for the `mount` command:

<code>-f</code>	Causes everything to be done except for the actual system call; if it's not obvious, this "fakes" mounting the filesystem. This option is useful in conjunction with the <code>-v</code> flag to determine what the <code>mount</code> command is trying to do.
<code>-o</code>	Options are specified with a <code>-o</code> flag followed by a comma-separated string of options. Note that many of these options are only useful when they appear in the <code>/etc/fstab</code> file. The following options apply to any filesystem that is being mounted:
<code>async</code>	All I/O to the filesystem should be done asynchronously.
<code>auto</code>	Can be mounted with the <code>-a</code> option.
<code>defaults</code>	Use default options: <code>rw</code> , <code>suid</code> , <code>dev</code> , <code>exec</code> , <code>auto</code> , <code>nouser</code> , and <code>async</code> .
<code>dev</code>	Interpret character or block special devices on the filesystem.
<code>exec</code>	Permit execution of binaries.
<code>noauto</code>	Can only be mounted explicitly (that is, the <code>-a</code> option does not cause the filesystem to be mounted).
<code>nodev</code>	Do not interpret character or block special devices on the filesystem. This option is useful for a server that has filesystems containing special devices for architectures other than its own.
<code>noexec</code>	Do not allow execution of any binaries on the mounted filesystem. This option is useful for a server that has filesystems containing binaries for architectures other than its own.
<code>nosuid</code>	Do not allow set-user-identifier or set-group-identifier bits to take effect.
<code>nouser</code>	Forbid an ordinary (that is, non-root) user to mount the filesystem.
<code>remount</code>	Attempt to remount an already-mounted filesystem. This is commonly used to change the mount flags for a filesystem, especially to make a read-only filesystem writable.
<code>ro</code>	Mount the filesystem read-only.
<code>rw</code>	Mount the filesystem read-write.
<code>suid</code>	Allow set-user-identifier or set-group-identifier bits to take effect.
<code>sync</code>	All I/O to the filesystem should be done synchronously.
<code>user</code>	Allow an ordinary user to mount the filesystem. Ordinary users always have the following options activated: <code>noexec</code> , <code>nosuid</code> , and <code>nodev</code> (unless overridden by the super-user by using, for example, the following option line: <code>user,exec,dev,suid</code>).

The following options apply only to certain filesystems:

<code>case=val ue</code>	For the <code>hpfs</code> filesystem, specify <code>case</code> as <code>lower</code> or <code>asis</code> .
<code>check=val ue</code>	Tells the <code>ext2</code> filesystem kernel code to do some more checks while the filesystem is mounted. Currently (0.99.15), the following values can be specified with this option:
<code>none</code>	No extra check is performed by the kernel code.
<code>normal</code>	The inodes and blocks bitmaps are checked when the filesystem is mounted (this is the default).
<code>strict</code>	In addition to the normal checks, block deallocation checks that the block to free is in the data zone.
<code>check=val ue</code>	For the <code>msdos</code> filesystem, three different levels of specificity can be chosen:

<code>relaxed</code>	Uppercase and lowercase are accepted and equivalent, long name parts are truncated (for example, <code>verLongname.foo</code> becomes <code>verylong.foo</code>), leading and embedded spaces are accepted in each name part (name and extension).
<code>normal</code>	Like <code>relaxed</code> but many special characters (<code>*</code> , <code>?</code> , <code><</code> , spaces, and so on) are rejected. This is the default.
<code>strict</code>	Like <code>normal</code> , but names may not contain long parts and special characters that are sometimes used on Linux but are not accepted by MS-DOS are rejected (<code>+</code> , <code>=</code> , spaces, and so on).
<code>conv=val ue</code>	For the <code>msdos</code> , <code>hpfs</code> , and <code>iso9660</code> filesystems, specify file conversion as <code>binary</code> , <code>text</code> , or <code>auto</code> . The <code>iso9660</code> filesystem also allows value to be <code>mtext</code> . The <code>msdos</code> filesystem can perform <code>CRLF<->NL</code> (MS-DOS text format to UNIX text format) conversion in the kernel. The following conversion modes are available:
<code>binary</code>	No translation is performed. This is the default.
<code>text</code>	<code>CRLF<->NL</code> translation is performed on all files.
<code>auto</code>	<code>CRLF<->NL</code> translation is performed on all files that don't have a well-known binary extension. The list of known extensions can be found at the beginning of <code>fs/msdos/misc.c</code> (as of 09913r, the list is <code>exe</code> , <code>com</code> , <code>bin</code> , <code>app</code> , <code>sys</code> , <code>drv</code> , <code>ovl</code> , <code>ovr</code> , <code>obj</code> , <code>lib</code> , <code>dll</code> , <code>pif</code> , <code>arc</code> , <code>zip</code> , <code>lha</code> , <code>lzh</code> , <code>zoo</code> , <code>tar</code> , <code>z</code> , <code>arj</code> , <code>tz</code> , <code>taz</code> , <code>tzp</code> , <code>tpz</code> , <code>gif</code> , <code>bmp</code> , <code>tif</code> , <code>gl</code> , <code>jpg</code> , <code>pcx</code> , <code>tfm</code> , <code>vf</code> , <code>gf</code> , <code>pk</code> , <code>pxl</code> , and <code>dvi</code>).

Programs that do computed `lseek`s won't like in-kernel text conversion.

For filesystems mounted in `binary` mode, a conversion tool (`fromdos/todos`) is available.

<code>block=val ue</code>	For the <code>iso9660</code> filesystem, set the block size.
<code>bsdgroups</code>	See <code>grpuid</code> .
<code>cruft</code>	For the <code>iso9660</code> filesystem, set the <code>cruft</code> flag to <code>y</code> . This option is available because there are buggy premastering programs out there that leave junk in the top byte of the file size. This option clears the top byte but restricts files to 16MB maximum in the process.
<code>debug</code>	For the <code>msdos</code> filesystem, turn on the <code>debug</code> flag. A version string and a list of filesystem parameters is printed. (These data are also printed if the parameters appear to be inconsistent.)
<code>debug</code>	For the <code>ext2fs</code> filesystem, cause the kernel code to display the filesystem parameters when the filesystem is mounted.
<code>errors=val ue</code>	For the <code>ext2fs</code> filesystem, specify the error behavior:
<code>continue</code>	No special action is taken on errors (except marking the filesystem as erroneous). This is the default.
<code>remount, ro</code>	The filesystem is remounted read only, and subsequent writes are refused.
<code>panic</code>	When an error is detected, the system panics.
<code>fat=val ue</code>	For the <code>msdos</code> filesystem, specify either a 12-bit fat or a 16-bit fat. This overrides the automatic FAT type detection routine. Use with caution!
<code>gid=val ue</code>	For the <code>msdos</code> and <code>hpfs</code> filesystems, give every file a <code>gid</code> equal to <code>val ue</code> .
<code>B grpuid</code>	Causes the <code>ext2fs</code> to use the BSD behavior when creating files: Files are created with the group ID of their parent directory.
<code>map=val ue</code>	For the <code>iso9660</code> filesystem, specify mapping as <code>off</code> or <code>normal</code> . In general, non-Rock Ridge discs have all the filenames in uppercase, and all the filenames have a <code>;1</code> appended. The <code>map</code> option strips the <code>;1</code> and makes the name lowercase. (See also <code>norock</code> .)
<code>nocheck</code>	For the <code>ext2fs</code> , turns off checking (see <code>check=none</code>).
<code>nogrpuid</code>	Causes the <code>ext2fs</code> to use the System V behavior when creating files. Files are created with the group ID of the creating process, unless the <code>setgid</code> bit is set on the parent directory. This is the default for all Linux filesystems.

norock	Normal <code>iso9660</code> filenames appear in a 8.3 format (that is, DOS-like restrictions on filename length), and in addition, all characters are in uppercase. Also there is no field for file ownership, protection, number of links, provision for block/character devices, and so on. Rock Ridge is an extension to <code>iso9660</code> that provides all of these UNIX-like features. Basically, there are extensions to each directory record that supply all of the additional information, and when Rock Ridge is in use, the filesystem is indistinguishable from a normal UNIX filesystem (except that it is read only, of course). The <code>norock</code> switch disables the use of Rock Ridge extensions, even if available. (See also <code>map</code> .)
quiet	For the <code>msdos</code> filesystem, turn on the <code>quiet</code> flag. Attempts to <code>chown</code> or <code>chmod</code> files do not yield errors, although they fail. Use with caution!
sb=val ue	For the <code>ext2</code> filesystem, use an alternate superblock located at block <code>val ue</code> . <code>val ue</code> is numbered in 1024-byte blocks. An <code>ext2</code> filesystem usually has backups of the superblock at blocks 1, 8193, 16385, and so on.
sysvgroups	See <code>nogrpuid</code> .
uid=val ue	For the <code>msdos</code> and <code>hpfs</code> filesystems, give every file a <code>uid</code> equal to <code>val ue</code> .
umask=val ue	For the <code>msdos</code> and <code>hpfs</code> filesystems, give every file a <code>umask</code> of <code>val ue</code> . The <code>radix</code> defaults to <code>octal</code> .

The full set of options applied is determined by first extracting the options for the filesystem from the `fstab` table, then applying any options specified by the `-o` argument, and finally applying the `-r` or `-w` option.

If the `msdos` filesystem detects an inconsistency, it reports an error and sets the filesystem to read only. The filesystem can be made writable again by remounting it.

<code>-r</code>	The filesystem object is to be mounted read only.
<code>-t vfstype</code>	The argument following the <code>-t</code> is used to indicate the filesystem type. The filesystem types that are currently supported are listed in <code>linux/fs/filesystems.c</code> : <code>minix</code> , <code>ext</code> , <code>ext2</code> , <code>xiafs</code> , <code>msdos</code> , <code>hpfs</code> , <code>proc</code> , <code>nfs</code> , <code>iso9660</code> , <code>sysv</code> , <code>xenix</code> , <code>coherent</code> . Note that that last three are equivalent and that <code>xenix</code> and <code>coherent</code> will be removed at some point in the future; use <code>sysv</code> instead. The type <code>minix</code> is the default. If no <code>-t</code> option is given, or if the <code>auto</code> type is specified, the superblock is probed for the filesystem type (<code>minix</code> , <code>ext</code> , <code>ext2</code> , and <code>xia</code> are supported). If this probe fails and <code>/proc/filesystems</code> exists, then all the filesystems listed are tried, except for those labeled <code>nodev</code> (such as <code>proc</code> and <code>nfs</code>). Note that the <code>auto</code> type may be useful for user-mounted floppies. For example, the <code>mount</code> command mounts all filesystems except those of type <code>msdos</code> and <code>ext</code> : <code>mount -a -t nomsgdos,ext</code>
<code>-v</code>	Verbose mode.
<code>-w</code>	The filesystem object is to be read and write.
<code>-n</code>	Mount without writing in <code>/etc/mtab</code> .

`umount` removes the special device grafted at point `node` from the filesystem tree.

Options for the `umount` command:

<code>-a</code>	All of the filesystems described in <code>/etc/mtab</code> are unmounted.
<code>-t vfstype</code>	Is used to indicate the actions should only be taken on filesystems of the specified type. More than one type may be specified in a comma-separated list. The list of filesystem types can be prefixed with <code>no</code> to specify the filesystem types on which no action should be taken. (See example for the <code>mount</code> command.)

FILES

<code>/etc/fstab</code>	Filesystem table
<code>/etc/mtab</code>	Lock file
<code>/etc/mtab.tmp</code>	Temporary file

SEE ALSO

`mount(2)`, `umount(2)`, `fstab(5)`, `swapon(8)`

BUGS

It is possible for a corrupted filesystem to cause a crash.

Some Linux filesystems don't support `-o synchronous` (the `ext2fs` does support synchronous updates (a la BSD) when mounted with the `sync` option).

The `-o remount` may not be able to change mount parameters (all `ext2fs` parameters, except `sb`, are changeable with a `remount`, for example, but you can't change `gid` or `umask` for the `dosfs`).

HISTORY

A `mount` command appeared in Version 6, AT&T UNIX.

AUTHORS AND CONTRIBUTORS

The Linux `mount` command has a long and continuing history. The following major releases are noted with the name of the primary modifier:

0.97.3: Doug Quale (quale@saavik.cs.wisc.edu)

0.98.5: H.J. Lu (hlu@eecs.wsu.edu)

0.99.2: Rick Sladkey (jrs@world.std.com)

0.99.6: Rick Sladkey (jrs@world.std.com)

0.99.10: Stephen Tweedie (sct@dcs.ed.ac.uk)

0.99.14: Rick Sladkey (jrs@world.std.com)

(Filesystem-specific information added to man page on 27 November 1993 by Rik Faith with a lot of information and text from the following filesystem authors: Werner Almesberger, Eric Youngdale, and Remy Card.)

Linux 1.1, 8 February 1995

mountd

mountd—NFS mount daemon.

SYNOPSIS

```

/usr/etc/rpc.mountd [-f|--exports-file][\ -dhnrpv\
[\ -debug][\ - -exports-file=file\] [\ -help\
[\ -allow-non-root\][\ -re-export\][\ -version\

```

DESCRIPTION

The `mountd` program is an NFS mount daemon.

OPTIONS

`-f` or `--exports-file` This option specifies the exports file, listing the clients that this server is prepared to serve and parameters to apply to each such mount (see `exports(5)`). By default, exports are read from `/etc/exports`.

<code>-d</code> OR <code>--debug</code>	Log each transaction verbosely to the <code>syslog</code> .
<code>-h</code> OR <code>--help</code>	Provide a short help summary.
<code>-n</code> OR <code>--allow-non-root</code>	Allow incoming mount requests to be honored even if they do not originate from reserved IP ports. Some older NFS client implementations require this. Some newer NFS client implementations don't believe in reserved port checking.
<code>-p</code> OR <code>--promiscuous</code>	Put the server into promiscuous mode where it will serve any host on the network.
<code>-r</code> OR <code>--re-export</code>	Allow imported NFS filesystems to be exported. This can be used to turn a machine into an NFS multiplier. Caution should be used when reexporting loopback NFS mounts because reentering the mount point results in deadlock between the NFS client and the NFS server.
<code>-v</code> OR <code>--version</code>	Report the current version number of the program.

SEE ALSO

`exports(5)`, `nfsd(8)`, `ugidd(8C)`

BUGS

The current implementation (still) does not keep track of remote mounts.

13 October 1993

named-xfer

`named-xfer`—Ancillary agent for inbound zone transfers.

SYNOPSIS

```
named-xfer -z zone_to_transfer -f db_file -s serial_no [ -d debuglevel ]
[-l debug_log_file ][-t trace_file ][-p port# ][-S ] nameserver
```

DESCRIPTION

`named-xfer` is an ancillary program executed by `named(8)` to perform an inbound zone transfer. It is rarely executed directly and only by system administrators who are trying to debug a zone transfer problem. See RFCs 1033, 1034, and 1035 for more information on the Internet name-domain system.

Options are

<code>-z</code>	Specifies the name of the zone to be transferred.
<code>-f</code>	Specifies the name of the file into which the zone should be dumped when it is received from the primary server.
<code>-s</code>	Specifies the serial number of the current copy of this zone. If the SOA RR you get from the primary server does not have a serial number higher than this, the transfer is aborted.
<code>-d</code>	Print debugging information. A number after the <code>d</code> determines the level of messages printed.
<code>-l</code>	Specifies a log file for debugging messages. The default is system-dependent but is usually in <code>/var/tmp</code> or <code>/usr/tmp</code> . Note that this only applies if <code>-d</code> is also specified.
<code>-t</code>	Specifies a trace file that contains a protocol trace of the zone transfer. This is probably only of interest to people debugging the nameserver itself.
<code>-p</code>	Use a different port number. The default is the standard port number as returned by <code>getservbyname(3)</code> for service “domain”.
<code>-S</code>	Perform a restricted transfer of only the SOA, NS records, and glue A records for the zone. The SOA record is not loaded by <code>named</code> but is used to determine when to verify the NS records. See the <code>stubs</code> directive in <code>named(8)</code> for more information.

Additional arguments are taken as nameserver addresses in so-called “dotted-quad” syntax only; no hostnames are allowed here. At least one address must be specified. Any additional addresses are tried in order if the first one fails to transfer successfully.

named

named—Internet domain nameserver.

SYNOPSIS

```
named [ -d debuglevel ][-p port#[/localport#]][{-b} bootfile ][-q ][-r ]
```

DESCRIPTION

named is the Internet domain nameserver. See RFCs 1033, 1034, and 1035 for more information on the Internet name-domain system. Without any arguments, named reads the default boot file `/etc/named.boot`, reads any initial data, and listens for queries.

Options are

- d Print debugging information. A number after the `d` determines the level of messages printed.
- p Use nonstandard port numbers. The default is the standard port number as returned by `getservbyname(3)` for service “domain”. The argument can specify two port numbers separated by a slash (`/`), in which case the first port is that used when contacting remote servers and the second one is the service port bound by the local instance of named. This is used mostly for debugging purposes.
- b Use an alternate boot file. This is optional and allows you to specify a file with a leading dash.
- q Trace all incoming queries if named has been compiled with `QUERYLOG` defined. Note that this option is deprecated in favor of the boot file directive `options query-log`.
- r Turns recursion off in the server. Answers can come only from local (primary or secondary) zones. This can be used on root servers. Note that this option is deprecated in favor of the boot file directive `options no-recursion`.

Any additional argument is taken as the name of the boot file. If multiple boot files are specified, only the last is used.

The boot file contains information about where the nameserver is to get its initial data. Lines in the boot file cannot be continued on subsequent lines. The following is a small example:

```

;
; boot file for name server
;
directory /usr/local/adm/named
; type domain source host/file backup file
cache . root.cache
primary Berkeley.EDU berkeley.edu.zone
primary 32.128.IN-ADDR.ARPA ucshosts.rev
secondary CC.Berkeley.EDU 128.32.137.8 128.32.137.3 cc.zone.bak
secondary 6.32.128.IN-ADDR.ARPA 128.32.137.8 128.32.137.3 cc.rev.bak
primary 0.0.127.IN-ADDR.ARPA localhost.rev
```

```
forwarders 10.0.0.78 10.2.0.78
limit transfers-in 10
limit datasize 64M
options forward-only query-log fake-iquery
```

The `directory` line causes the server to change its working directory to the directory specified. This can be important for the correct processing of `$INCLUDE` files in primary zone files.

The `cache` line specifies that data in `root.cache` is to be placed in the backup cache.

Its main use is to specify data such as locations of root domain servers. This cache is not used during normal operation, but is used as “hints” to find the current root servers. The file `root.cache` is in the same format as `berkeley.edu.zone`. There can be more than one `cache` file specified. The `root.cache` file should be retrieved periodically from `FTP.RS.INTERNIC.NET` because it contains a list of root servers, and this list changes periodically.

The first sample `primary` line states that the file `berkeley.edu.zone` contains authoritative data for the `Berkeley.EDU` zone. The file `berkeley.edu.zone` contains data in the master file format described in RFC 883. All domain names are relative to the origin, in this case, `Berkeley.EDU` (see below for a more detailed description). The second `primary` line states that the file `ucbhosts.rev` contains authoritative data for the domain `32.128.IN-ADDR.ARPA`, which is used to translate addresses in network `128.32` to hostnames. Each master file should begin with an SOA record for the zone (see below).

The first sample `secondary` line specifies that all authoritative data under `CC.Berkeley.EDU` is to be transferred from the nameserver at `128.32.137.8`. If the transfer fails, it tries `128.32.137.3` and continues trying the addresses, up to ten, listed on this line. The secondary copy is also authoritative for the specified domain. The first non-dotted-quad address on this line is taken as a filename in which to back up the transferred zone. The nameserver loads the zone from this backup file if it exists when it boots, providing a complete copy even if the master servers are unreachable. Whenever a new copy of the domain is received by automatic zone transfer from one of the master servers, this file is updated. If no filename is given, a temporary file is used and deleted after each successful zone transfer. This is not recommended because it is a needless waste of bandwidth. The second sample `secondary` line states that the address-to-hostname mapping for the subnet `128.32.136` should be obtained from the same list of master servers as the previous zone.

The `forwarders` line specifies the addresses of sitewide servers that will accept recursive queries from other servers. If the boot file specifies one or more forwarders, then the server sends all queries for data not in the cache to the forwarders first. Each forwarder is asked in turn until an answer is returned or the list is exhausted. If no answer is forthcoming from a forwarder, the server continues as it would have without the `forwarders` line unless it is in `forward-only` mode. The forwarding facility is useful to cause a large sitewide cache to be generated on a master and to reduce traffic over links to outside servers. It can also be used to allow servers to run that do not have direct access to the Internet but want to look up exterior names anyway.

The `slave` line (deprecated) is allowed for backward compatibility. Its meaning is identical to `options forward-only`.

The `sortlist` line can be used to indicate networks that are to be preferred over other networks. Queries for host addresses from hosts on the same network as the server receive responses with local network addresses listed first, then addresses on the sort list, and then other addresses.

The `xfrnets` directive (not shown) can be used to implement primitive access control. If this directive is given, your nameserver only answers zone transfer requests from hosts that are on networks listed in your `xfrnets` directives. This directive may also be given as `tcplist` for compatibility with older, interim servers.

The `include` directive (not shown) can be used to process the contents of some other file as though they appeared in place of the `include` directive. This is useful if you have a lot of zones or if you have logical groupings of zones that are maintained by different people. The `include` directive takes one argument, the name of the file whose contents are to be included. No quotes are necessary around the filename.

The `bogusns` directive (not shown) tells BIND that no queries are to be sent to the specified nameserver addresses (which are specified as dotted quads, not as domain names). This is useful when you know that some popular server has bad data in a zone or cache, and you want to avoid contamination while the problem is being fixed.

The `limit` directive can be used to change BIND’s internal limits, some of which (`datasize`, for example) are implemented by the system and others (such as `transfers-in`) by BIND itself. The number following the limit name can be scaled by

postfixing a `k`, `m`, or `g` for kilobytes, megabytes, and gigabytes respectively. `datasize`'s argument sets the process data size enforced by the kernel. Note that not all systems provide a call to implement this; on such systems, the use of the `datasize` parameter of `limit` results in a warning message. `transfers-in`'s argument is the number of `named-xfer` subprocesses that BIND will spawn at any one time. `transfers-per-ns`'s argument is the maximum number of zone transfers to be simultaneously initiated to any given remote nameserver.

The `options` directive introduces a Boolean specifier that changes the behavior of BIND. More than one option can be specified in a single directive. The currently defined options are as follows: `no-recursion`, which causes BIND to answer with a referral rather than actual data whenever it receives a query for a name it is not authoritative for. Don't set this on a server that is listed in any host's `resolv.conf` file. `no-fetch-glue` keeps BIND from fetching missing glue when constructing the "additional data" section of a response; this can be used in conjunction with `no-recursion` to prevent BIND's cache from ever growing in size or becoming corrupted. `query-log` causes all queries to be logged via `syslog(3)`. This is a lot of data; don't turn it on lightly. `forward-only` causes the server to query only its forwarders. This option is usually used on a machine that wants to run a server but for physical or administrative reasons cannot be given access to the Internet. `fake-iquery` tells BIND to send back a useless and bogus reply to "inverse queries" rather than respond with an error. This is helpful if you have a lot of microcomputers or SunOS hosts or both.

The `max-fetch` directive (not shown) is allowed for backward compatibility; its meaning is identical to `limit transfers-in`.

The master file consists of control information and a list of resource records for objects in the zone of the forms:

```
$INCLUDE <filename><opt_domain>
$ORIGIN <domain>
<domain><opt_ttl> <opt_class><type><resource_record_data>
```

`domain` is `.` for root, `@` for the current origin, or a standard domain name. If `domain` is a standard domain name that does not end with `.`, the current origin is appended to the domain. Domain names ending with `.` are unmodified. The `opt_domain` field is used to define an origin for the data in an included file. It is equivalent to placing a `$ORIGIN` statement before the first line of the included file. The field is optional. Neither the `opt_domain` field nor `$ORIGIN` statements in the included file modify the current origin for this file. The `opt_ttl` field is an optional integer number for the time-to-live field. It defaults to `0`, meaning the minimum value specified in the SOA record for the zone. The `opt_class` field is the object address type; currently only one type is supported, `IN`, for objects connected to the DARPA Internet. The type field contains one of the following tokens; the data expected in the `resource_record_data` field is in parentheses:

A	A host address (dotted quad).
NS	An authoritative nameserver (domain).
MX	A mail exchanger (domain), preceded by a preference value (0..32767) with lower numeric values representing higher logical preferences.
CNAME	The canonical name for an alias (domain).
SOA	Marks the start of a zone of authority (domain of originating host, domain address of maintainer, a serial number and the following parameters in seconds: <code>refresh</code> , <code>retry</code> , <code>expire</code> , and <code>minimum TTL</code> (see RFC 883)).
NULL	A null resource record (no format or data).
RP	A responsible person for some domain name (<code>mailbox</code> , <code>TXT-referral</code>).
PTR	A domain name pointer (domain).
HINFO	Host information (<code>cpu_type</code> , <code>OS_type</code>).

Resource records usually end at the end of a line but may be continued across lines between opening and closing parentheses. Comments are introduced by semicolons and continue to the end of the line.

Note that there are other resource record types, not shown here. You should consult the BIND Operations GUIDE (BOG) for the complete list. Some resource record types may have been standardized in newer RFCs but not yet implemented in this version of BIND.

Each master zone file should begin with an SOA record for the zone. A sample SOA record follows:

```
@ IN SOA ucbvax.Berkeley.EDU. rwh.ucbvax.Berkeley.EDU. (
1989020501 ; serial
10800 ; refresh
3600 ; retry
3600000 ; expire
86400 ) ; minimum
```

The SOA specifies a serial number, which should be changed each time the master file is changed. Note that the serial number can be given as a dotted number, but this is a very unwise thing to do because the translation to normal integers is via concatenation rather than multiplication and addition. You can spell out the year, month, day of month, and 0..99 version number and still fit inside the unsigned 32-bit size of this field. It's true that we will have to rethink this strategy in the year 4294, but we're not worried about it. Secondary servers check the serial number at intervals specified by the refresh time in seconds; if the serial number changes, a zone transfer is done to load the new data. If a master server cannot be contacted when a refresh is due, the retry time specifies the interval at which refreshes should be attempted. If a master server cannot be contacted within the interval given by the expire time, all data from the zone is discarded by secondary servers. The minimum value is the time-to-live (TTL) used by records in the file with no explicit time-to-live value.

NOTES

The boot file directives `domain` and `suffixes` have been obsoleted by a more useful resolver-based implementation of suffixing for partially qualified domain names. The prior mechanisms could fail under a number of situations, especially when the local nameserver did not have complete information.

The following signals have the specified effect when sent to the server process using the `kill(1)` command:

SIGHUP	Causes server to read <code>named.boot</code> and reload the database. If the server is built with the <code>FORCED RELOAD</code> compile-time option, then SIGHUP also causes the server to check the serial number on all secondary zones. Usually, the serial numbers are only checked at the SOA-specified intervals.
SIGINT	Dumps the current database and cache to <code>/var/tmp/named_dump.db</code> .
SIGIOT	Dumps statistics data into <code>/var/tmp/named.stats</code> if the server is compiled with <code>-DSTATS</code> . Statistics data is appended to the file. Some systems use <code>SIGABRT</code> rather than <code>SIGIOT</code> for this.
SIGSYS	Dumps the profiling data in <code>/var/tmp</code> if the server is compiled with profiling (the server forks, changes directories, and exits).
SIGTERM	Dumps the primary and secondary database files. Used to save modified data on shutdown if the server is compiled with dynamic updating enabled.
SIGUSR1	Turns on debugging; each SIGUSR1 increments debug level (SIGEMT on older systems without SIGUSR1).
SIGUSR2	Turns off debugging completely (SIGFPE on older systems without SIGUSR2).
SIGWINCH	Toggles logging of all incoming queries via <code>syslog(3)</code> (requires server to have been built with the <code>QRYLOG</code> option).

FILES

<code>/etc/named.boot</code>	Nameserver configuration boot file
<code>/etc/named.pid</code>	The process ID (on older systems)
<code>/var/run/named.pid</code>	The process ID (on newer systems)
<code>/var/tmp/named_dump.db</code>	Dump of the nameserver database
<code>/var/tmp/named.run</code>	Debug output
<code>/var/tmp/named.stats</code>	Nameserver statistics data

named.reload

named.reload—Cause the nameserver to synchronize its database.

DESCRIPTION

This command sends a `SIGHUP` to the running nameserver. This signal is documented in `named(8)`.

BUGS

It does not check to see if the nameserver is actually running and could use a stale pid cache file, which may result in the death of an unrelated process.

SEE ALSO

named(8), named.restart(8)

26 June 1993

named.restart

named.restart—Stop and restart the nameserver.

DESCRIPTION

This command sends a `SIGKILL` to the running nameserver and then starts a new one.

BUGS

It does not check to see if the nameserver is actually running and could use a stale pid cache file, which may result in the death of an unrelated process.

It does not wait after killing the old server before starting a new one. Because the server could take some time to die and the new one experiences a fatal error if the old one isn't gone by the time it starts, you can be left in a situation where you have no nameserver at all.

SEE ALSO

named(8), named.reload(8)

26 June 1993

ndc

ndc—Name daemon control interface.

SYNOPSIS

ndc directive [...]

DESCRIPTION

This command allows the nameserver administrator to send various signals to the nameserver or to restart it. Zero or more directives may be given from the following list:

status	Displays the current status of named as shown by <code>ps(1)</code> .
dumpdb	Causes named to dump its database and cache to <code>/var/tmp/named_dump.db</code> (uses the <code>INT</code> signal.)
reload	Causes named to check the serial numbers of all primary and secondary zones and to reload those that have changed (uses the <code>HUP</code> signal.)
stats	Causes named to dump its statistics to <code>/var/tmp/named.stats</code> (uses the <code>IOT</code> or <code>ABRT</code> signal.)
trace	Causes named to increment its “tracing level” by one. Whenever the tracing level is nonzero, trace information is written to <code>/var/tmp/named.run</code> . Higher tracing levels result in more detailed information (uses the <code>USR1</code> signal).
notrace	Causes named to set its “tracing level” to zero, closing <code>/var/tmp/named.run</code> if it is open (uses the <code>USR2</code> signal).
querylog	Causes named to toggle the “query logging” feature, which results in a <code>syslog(3)</code> of each incoming query (uses the <code>WINCH</code> signal). Note that query logging consumes quite a lot of log file space. This directive may also be given as <code>qrylog</code> .
start	Causes named to be started as long as it isn't already running.
stop	Causes named to be stopped if it is running.
restart	Causes named to be killed and restarted.

BUGS

Arguments to `named` are not preserved by `restart` or known by `start`. Some mechanism for controlling the parameters and environment should exist.

Implemented as a `sh(1)` script.

AUTHOR

Paul Vixie (Internet Software Consortium)

netstat

`netstat`—Display active network connections

SYNOPSIS

```
netstat [[-a | [-t | -u | -w]] [-n | -o] | -x] [-c]
netstat -r [-c] [-n]
netstat -v
```

DESCRIPTION

`netstat` displays the status of network connections on either TCP, UDP, or RAW sockets to the system. By default, `netstat` only displays status on those TCP sockets that are not in the `LISTEN` state (that is, connections to active processes). To obtain information about the kernel routing table, `netstat` may be invoked with the option `-r`. A listing of internal UNIX connections can be obtained by invoking `netstat` with the option `-x`.

`netstat`'s display includes the following information for each socket:

Proto	The protocol (either TCP or UDP) used by the socket.
Recv-Q	The count of bytes not copied by the user program connected to this socket.
Send-Q	The count of bytes not acknowledged by the remote host.
Local Address	The local address (local hostname) and port number of the socket. Unless the <code>-n</code> switch is given, the socket address is resolved to its canonical hostname, and the port number is translated into the corresponding service name.
Foreign Address	The remote address (remote hostname) and port number of the socket. As with the local <code>address:port</code> , the <code>-n</code> switch turns off hostname and service name resolution.
(State)	The state of the socket. Because there are no states in RAW and usually no states used in UDP, this row may be left blank. Usually, this can be one of several values:
ESTABLISHED	The socket has an established connection.
SYN SENT	The socket is actively attempting to establish a connection.
SYN RECV	The connection is being initialized.
FIN WAIT1	The socket is closed, and the connection is shutting down.
FIN WAIT2	Connection is closed, and the socket is waiting for a shutdown from the remote end.
TIME WAIT	The socket is waiting after close for remote shutdown re-transmission.
CLOSED	The socket is not being used.
CLOSE WAIT	The remote end has shut down, waiting for the socket to close.
LAST ACK	The remote end shut down, and the socket is closed. Waiting for acknowledgment.
LISTEN	The socket is listening for incoming connections.
UNKNOWN	The state of the socket is unknown.

If `netstat` is invoked with the option `-o`, additional information is displayed after the state info. This information is shown like this: keyword (time/backoff) and an optional asterisk. The keyword shows the state of the timer belonging to the socket, the time displayed (in seconds) is how long it will take the timer to expire, the backoff value indicates the current retry count for data transmission, and the asterisk indicates that this timer is in the expiration queue. The latter might be removed in future but is helpful for debugging the TCP-Code for now.

Invoked with the option `-x`, `netstat` displays a list of all active UNIX internal communication sockets.

`netstat`'s display includes the following information for each socket:

Proto	The protocol (usually UNIX) used by the socket.
RefCnt	The reference count (attached processes via this socket).
Flags	The only known flag to me is <code>SO_ACCEPTON</code> (displayed as <code>ACC</code>); otherwise, left blank. <code>SO_ACCEPTON</code> is used on unconnected sockets if their corresponding processes are waiting for a connect request.
Type	There are several types of socket access:
SOCK_DGRAM	The socket is used in Datagram (connectionless) mode.
SOCK_STREAM	This is a stream (connection) socket.
SOCK_RAW	The socket is used as a raw socket.
SOCK_RDM	This one serves reliably delivered messages.
SOCK_SEQPACKET	This is a sequential packet socket.
SOCK_PACKET	This socket type is used as a Linux-specific way to get packets at the dev (kernel) level. It is assumed to be used to write things such as RARP (Reverse Address Resolution Protocol) and similar things on the user level.
UNKNOWN	Who ever knows, what future will bring; just fill in here. :-)
State	This field will contain one of the following keywords:
FREE	The socket is not allocated.

LISTENING	The socket is listening for a connection request.
UNCONNECTED	The socket is not connected to another one.
CONNECTING	The socket is about to establish a connection.
CONNECTED	The socket is connected.
DISCONNECTING	The socket is disconnecting.
UNKNOWN	This state should never happen.
Path	This displays the pathname that the corresponding processes attached to the socket.

The network routing table (invoked with `netstat -r`) shows up the following information:

Destination net/address	The destination address of a resolved host or hand-entered network is displayed. Unless the option <code>-n</code> is given, the hosts or nets are resolved. An entry named <code>default</code> shows up the default route for the kernel.
Gateway address	If there is no asterisk (*) displayed, any data is routed to the dedicated gateway.
Flags	Possible routing flags are <ul style="list-style-type: none"> U This route is usable. G Destination is a gateway. H Destination is a host entry. N Destination is a Net entry. R Route will be reinstated after timeout. D This one is created dynamically (by redirection). M This one is modified dynamically (by redirection).
RefCnt	Reference count for this route.
Use	How many times this route was used yet.
Iface	This is the name of the interface where this route belongs.

OPTIONS

-a	Display information about all Internet sockets, such as TCP, UDP, and RAW, including those sockets that are listening only.
-c	Generate a continuous listing of network status: network status is displayed every second until the program is interrupted.
-n	Causes <code>netstat</code> not to resolve hostnames and service names when displaying remote and local address and port information.
-o	Display timer states, expiration times, and backoff state.
-r	Display kernel routing table.
-t	Display information about TCP sockets only, including those that are listening.
-u	Display information about UDP sockets only.
-v	Print version information.
-w	Display information about raw sockets.
-x	Display information about UNIX domain sockets.

FILES

<code>/proc/net/tcp</code>	TCP socket information
<code>/proc/net/udp</code>	UDP socket information
<code>/proc/net/raw</code>	RAW socket information
<code>/proc/net/unix</code>	UNIX domain socket information

<code>/proc/net/route</code>	Kernel routing information
<code>/etc/services</code>	The services translation

BUGS

None reported yet (5/20/93).

AUTHORS

The `netstat` user interface was written by Fred Baumgarten (`do6iq@insu1.etec.uni-karlsruhe.de`). The man page is basically by Matt Welsh (`mdw@tc.cornell.edu`).

Cohesive Systems, 20 May 1993

makeactive, makehistory, newsrequeue

makeactive, makehistory, newsrequeue—Tools to recover Usenet databases

SYNOPSIS

```
makeactive [ -m ][-o ]
makehistory [ -b ][-f filename ][-i ][-n ][-o ][-r ][-s size ]
[-T tmpdir ][-u [ -v]]
newsrequeue [ -a active ][-h history ][-d days ][-l ][-n newsfeeds ][input ]
```

DESCRIPTION

`makeactive` invokes `find(1)` to get a list of all directories in the news spool tree, `/news/spool`. It discards directories named `lost+found` as well as those that have a period in them. It scans all other directories for all-numeric filenames and determines the highest and lowest number. The program's output is a set of `active(5)` file lines. Because there is no way to know if a group is moderated or disabled, the fourth field of all entries is `y`. Also, mid-level directories that aren't newsgroups are also created as newsgroups with no entries. (For example, there is a `comp.sources.unix` group, but no `comp.sources`.)

If the `-o` flag is used, `makeactive` reads an existing active file for the list of group names and just renumber all groups. It preserves the fourth field of the active file if one is present. This is analogous to the `ctlinnd(8)` `renumber` command, except that `innd(8)` should be throttled or not running. Do not use this flag with output redirected to the standard active file!

If the `-m` flag is given, then `makeactive` attempts to adjust the highest and lowest article numbers wherever possible. If articles are found in a newsgroup, the numbers reflect what was found. If no articles are found in a newsgroup, the high number from the old file is kept, and the low number is set to one more than the high number. This flag may only be used if the `-o` flag is used.

`makeactive` exits with nonzero status if any problems occur. A typical way to use the program is with the following `/bin/sh` commands:

```
ctlinnd throttle "Rebuilding active file"
TEMP=${TMPDIR-/tmp}/act$$
if [ -f /var/lib/news/active ] ; then
    if makeactive -o >${TEMP} ; then
        mv ${TEMP} /var/lib/news/active
    fi
else
    if makeactive >${TEMP} ; then
        # Edit to restore moderated
        # and aliased groups.
        ...
        mv ${TEMP} /var/lib/news/active
    fi
fi
ctlinnd reload active "New active file"
```

makehistory rebuilds the history(5) text file and the associated dbz(3) database. The default name of the text file is /news/lib/history; to specify a different name, use the -f flag. makehistory scans the active(5) file to determine which newsgroup directories within the spool directory, /news/spool, should be scanned. (If a group is removed, but its spool directory still exists, makehistory ignores it.) The program reads each file found and writes a history line for it. If the -b flag is used, then makehistory removes any articles that do not have valid Message-ID headers in them.

After the text file is written, makehistory builds the dbz database. If the -f flag is used, then the database files are named file.dir and file.pag. If the -f flag is not used, then a temporary link to the name history.n is made and the database files are written as history.n.pag and history.n.dir. If the -o flag is used, then the link is not made and any existing history files are overwritten. If the old database exists, makehistory uses it to determine the size of the new database. To ignore the old database, use the -i flag. Using the -o flag implies the -i flag. The program also ignores any old database if the -s flag is used to specify the approximate number of entries in the new database. Accurately specifying the size is an optimization that creates a more efficient database. (The size should be the estimated eventual size of the file, typically the size of the old file.) For more information, see the discussion of dbzfresh and dbzsize in dbz(3).

If the -u flag is given, then makehistory assumes that innd is running. It pauses the server while scanning and then sends addhist commands (see ctlinnd(8)) to the server for any article that is not found in the dbz database. The command makehistory -bu is useful after a system crash to delete any mangled articles and bring the article database back into a more consistent state. If the -v flag is used with the -u flag, then makehistory puts a copy of all added lines on its standard output.

To scan the spool directory without rebuilding the dbz files, use the -n flag. If used with -u, the server is not paused while scanning. To just build the dbz files from an existing text file, use the -r flag. The -i or -s flags can be useful if there are no valid dbz files to use. A typical way to use this program is with the following /bin/sh commands:

```
ctlinnd throttle "Rebuilding history file"
cd /news/lib
if makehistory -n -f history.n ; then
:
else
echo Error creating history file!
exit 1
fi
# The following line can be used to retain expired history.
# It is not necessary for the history file to be sorted.
# awk 'NF==2 { print; }' <history >>history.n
# View history file for mistakes.
if makehistory -r -s 'wc -l <history' -f history.n; then
mv history.n history
mv history.n.dir history.dir
mv history.n.pag history.pag
fi
ctlinnd go "
```

makehistory needs to create a temporary file that contains one line for each article it finds, which can become very large. This file is created in the /tmp directory. The TMPDIR environment variable may be used to specify a different directory. Alternatively, the -T flag may be used to specify a temporary directory. In addition, the sort(1) that is invoked during the build writes large temporary files (often to /var/tmp, but see your system man pages). If the -T flag is used, then the flag and its value are passed to sort. On most systems, this changes the temporary directory that sort uses. If used, this flag and its value are passed on to the sort(1) command that is invoked during the build.

makehistory does not handle symbolic links. If the news spool area is split across multiple partitions, the following commands should probably be run before the database is regenerated:

```
cd /news/spool
find . -type l -name '[1-9]*' -print | xargs -t rm
```

Make sure to run the command on all the appropriate partitions!

`newsrqueue` can be used to rewrite batchfiles after a system crash. It operates in two modes. In the first mode, it first reads the `active` and `newsfeeds(5)` files to determine where the different newsgroups are to be distributed. To specify alternate locations for these files, use the `-a` or `-n` flags. It then opens the `history` database. To specify a different file, use the `-h` flag.

Once the files are opened, `newsrqueue` reads from the specified `input` file or standard input if no file is specified. Each line should have a single Message-ID, surrounded in angle brackets; any other text on the line is ignored. For example, the `history` file (or a trailing subset of it) is acceptable input to the program operating in this mode. If the `-d` flag is used, then only articles that were received within the specified number of days are processed.

`newsrqueue` uses the first two fields of the `newsfeed` entry—the `sitename` and the `excludes` field and the `patterns` and `distrib` field. It ignores all flags in the third field except for the `N` field and also ignores the fourth field altogether.

The second mode is used if the `-l` flag is used. In this mode, it reads from the specified `input` file or standard input if no file is specified. Each line should look like an `innd` log entry. It parses entries for accepted articles, looks up the Message-ID in the history database to get the filename, and then scans the list of sites.

In either mode, the output of `newsrqueue` consists of one line for each article that should be forwarded. Each such line contains the Message-ID, the filename, and the list of sites that should receive the article. The output is suitable for piping into `filechan(8)`.

news.daily

`news.daily`—Do regular Usenet system administration

SYNOPSIS

```
news.daily [ keyword... ]
innwatch [ -t sleeptime ][-f control file ][-l logfile ]
expirerm file
inncheck [ -v ][-pedantic ][-perms [ -fix ]][-noperms ][file... ]
```

DESCRIPTION

`news.daily` performs a number of important Usenet administrative functions. This includes producing a status report, removing old news articles, processing log files, rotating the archived log files, renumbering the active file, removing any old socket files found in the firewall directory, and collecting the output. This program should be run under the news administrator's ID, not as root.

By default, `news.daily` performs all its functions and mails the output to the news administrator, `usenet`. By specifying keywords on the command line, it is possible to modify the functions performed, as well as change the arguments given to `expire(8)` and `expireover(8)`.

`news.daily` should be run once a day, typically out of `cron(8)`. It may be run more often, but such invocations should at least use the `norotate` keyword to prevent the log files from being processed and rotated too fast.

The `shlock(1)` program is used to prevent simultaneous executions.

The following keywords may be used:

<code>delayrm</code>	This uses the <code>-z</code> flag when invoking <code>expire</code> and <code>expireover</code> . The names of articles to be removed are written to a temporary file and then removed after expiration by calling <code>expirerm</code> .
----------------------	---

nostat	This keyword disables the status report generated by innstat (see <code>newslog(8)</code>). Without this keyword, the status report is the first function performed, just prior to obtaining the <code>news.daily</code> lock.
noexpire	By default, <code>expire</code> is invoked to remove old news articles. Using this keyword disables this function.
noexplog	<code>expire</code> usually appends information to <code>/var/log/news/expire.log</code> (see <code>newslog(5)</code>). Using this keyword causes the <code>expire</code> output to be handled as part of <code>news.daily</code> 's output. It has no effect if the <code>noexpire</code> keyword is used.
flags='expire\args'	By default, <code>expire</code> is invoked with the an argument of <code>-v1</code> . Using this keyword changes the arguments to those specified. Be careful to use quotes if multiple arguments are needed. This keyword has no effect if the <code>noexpire</code> keyword is used.
nologs	After expiration, <code>scanlogs(8)</code> is invoked to process the log files. Using this keyword disables all log processing functions.
norotate	By default, log processing includes rotating and cleaning out log files. Using this keyword disables the rotating and cleaning aspect of the log processing. The log files are only scanned for information and no contents are altered. This keyword has no effect if the <code>nologs</code> keyword is used.
norenumber	This keyword disables the <code>ctlinnd(8)</code> renumber operation. Usually, the low watermark for all newsgroups (see <code>active(5)</code>) is reset.
norm	By default, any socket <code>ctlinnd</code> socket that has not been modified for two days is removed. Using this keyword disables this function.
nomail	<code>news.daily</code> usually sends a mail message containing the results to the administrator. Using this keyword causes this message to be sent to <code>stdout</code> and <code>stderr</code> instead. Usually, all utilities invoked by the script have their <code>stdout</code> and <code>stderr</code> redirected into a file. If the file is empty, no message is sent.
expireover	The <code>expireover</code> program is called after expiration to purge the overview databases.
expireoverflags='expireovernargs'	If the <code>expireover</code> keyword is used, this keyword may be used to specify the flags to be passed to <code>expireover</code> . If the <code>delayrm</code> keyword is used, then the default value is <code>-z</code> and the list of deleted files; otherwise, the default value is <code>-s</code> .
/full/path	The program specified by the given path is executed just before any expiration is done. A typical use is to specify an alternate expiration program and use the <code>noexpire</code> keyword. Multiple programs may be specified; they are invoked in order.

The `norotate` keyword is passed on to `scanlogs` if it is invoked. `expirerm` is a script that removes a list of files. The specified file lists the files. It is sorted and then fed into a pipeline responsible for doing the removal, usually `fastrm(8)`. If there seemed to be a problem removing the files, then mail is sent to the news administrator. If there were no problems, then file is renamed to `/var/log/news/expire.list` where it is kept (for safety) until the next day's expiration.

`innwatch` is a script that can be started at news boot time. It periodically—every `sleep` time seconds—examines the load average and the number of free blocks and inodes on the spool partition, as described by its control file, `innwatchctl(5)`. If the load gets too high or the disk gets too full, it throttles the server. When the condition restores, it unblocks the server. In addition, on each pass through the loop, it checks the specified log file to see if it has been modified and sends mail to the news administrator if so. It is usually a good idea to set this to the `syslog(3)` file that receives critical news messages. Upon receipt of an interrupt signal, `innwatch` reports its status in the file `/news/lib/innwatch.status`.

`inncheck` is a `perl(1)` script that verifies the syntax and permissions of all InterNetNews configuration files. If no files are specified, it checks all files. A filename may be followed by an equal sign and a path to indicate the pathname to use for the file. For example, `newsfeeds=/tmp/nf` checks the syntax of a new `newsfeeds(5)` without requiring it to be installed. If the `-v` flag is used, it prints status information as it checks each file. If the `-pedantic` flag is used, it checks the files for omissions that are not strictly errors but might indicate a configuration error.

If any file is specified, only the permissions on those files are checked. The `-noperms` flag suppresses this check. If the `-perms` flag is used, the script verifies the ownership and permissions of all files. The `-fix` flag can also be used so that the output can be executed as a shell script.

HISTORY

`news.daily` and this manual page were written by Landon Curt Noll (chongo@toad.com) and Rich Salz (rsalz@uunet.uu.net).
`inncheck` was written by Brendan Kehoe (brendan@cs.widener.edu) and Rich.
`innwatch` was written by Mike Cooper (mcooper@usc.edu) and (kre@munnari.oz.au).

newslog

newslog—Maintenance of Usenet log files

SYNOPSIS

```
scanlogs [ norotate ][nonn ]
writelog name text...
innstat
tally.unwanted
tally.control
innlog.awk
```

DESCRIPTION

`scanlogs` summarizes the information recorded in the INN log files (see `newslog(5)`). By default, it also rotates and cleans out the logs. It is usually invoked by the `news.daily(8)` script.

The following keywords are accepted:

<code>norotate</code>	Using this keyword disables the rotating and cleaning aspect of the log processing. The logs files are only scanned for information and no contents are altered.
<code>nonn</code>	Usually, the <code>nn</code> log file is scanned and rotated. Using this keyword disables this function.

If `scanlogs` is invoked more than once a day, the `norotate` keyword should be used to prevent premature log cleaning.

The `writelog` script is used to write a log entry or send it as mail. The `name` parameter specifies the name of the log file where the entry should be written. If it is the word `mail`, then the entry is mailed to the news administrator, Usenet. The data that is written or sent consists of the text given on the command line, followed by standard input indented by four spaces.

`shlock(1)` is used to avoid simultaneous updates to a single log file.

The `innstat` script prints a snapshot of the INN system. It displays the operating mode of the server, as well as disk usage and the status of all log and lock files.

The rest of the scripts described here are usually invoked by `scanlogs`. They parse log files that are described in `newslog(5)` and the server's article log file described in `innd(8)`.

`tally.unwanted` script parses the article log file to update the cumulative list of articles posted to unwanted newsgroups, `unwanted.log`.

`tally.control` reads its standard input, which should be the `newgroup.log` and `rmgroup.log` log files. It updates the cumulative list of newsgroup creations and deletions, `control.log`.

`innlog.awk` is an `awk(1)` script that summarizes the activity that `innd` and `nnrpd(8)` report to `syslog`.

HISTORY

nfsd

nfsd—NFS service daemon.

SYNOPSIS

```
/usr/etc/rpc.nfsd [-f\exports-file\][\-dhnrpv\]
[\--debug\][\--exports-file=file\] [\--help\]
[\--allow-non-root\][\--re-export\][\--version\]
```

DESCRIPTION

The `nfsd` program is an NFS service daemon that handles client filesystem requests. Unlike `nfsd` on some other systems, `nfsd` operates as a normal user-level process. The server also differs from other NFS server implementations in that it mounts an entire file hierarchy not limited by the boundaries of physical filesystems. The implementation allows the clients read-only or read-write access to the file hierarchy of the server machine.

The `mountd` program starts an ancillary user-level mount daemon.

OPTIONS

<code>-f</code> OR <code>--exports-file</code>	This option specifies the exports file, listing the clients that this server is prepared to serve and parameters to apply to each such mount (see <code>exports(5)</code>). By default, exports are read from <code>/etc/exports</code> .
<code>-d</code> OR <code>--debug</code>	Log each transaction verbosely to the <code>syslog</code> .
<code>-h</code> OR <code>--help</code>	Provide a short help summary.
<code>-n</code> OR <code>--allow-non-root</code>	Allow incoming NFS requests to be honored even if they do not originate from reserved IP ports. Some older NFS client implementations require this. Some newer NFS client implementations don't believe in reserved port checking.
<code>-p</code> OR <code>--promiscuous</code>	Put the server into promiscuous mode where it serves any host on the network.
<code>-r</code> OR <code>--re-export</code>	Allow imported NFS filesystems to be exported. This can be used to turn a machine into an NFS multiplier. Caution should be used when re-exporting loopback NFS mounts because re-entering the mount point results in deadlock between the NFS client and the NFS server.
<code>-v</code> OR <code>--version</code>	Report the current version number of the program.

SEE ALSO

exports(5), mountd(8), ugid(8C)

AUTHORS

Mark Shand wrote the original `unfsd`. Don Becker extended `unfsd` to support authentication and allow read-write access and called it `hnfs`. Rick Sladkey added host matching, `showmount -e` support, `mountd` authentication, `inetd` support, and all the portability and configuration code.

13 October 1993

nnrpd

nnrpd—NNTP server for on-campus hosts.

SYNOPSIS

```
nnrpd [ -r reason ][-s title padding ][-S host ][-t ]
```

DESCRIPTION

`nnrpd` is an NNTP server for newsreaders. It accepts commands on its standard input and responds on its standard output. It is usually invoked by `innd(8)` with those descriptors attached to a remote client connection.

If the `-r` flag is used, then `nnrpd` rejects the incoming connection giving `reason` as the text. This flag is used by `innd` when it is paused or throttled.

Unlike `innd`, `nnrpd` supports all NNTP commands for user-oriented reading and posting.

`nnrpd` uses the `nnrp.access(5)` file to control who is authorized to access the Usenet database. It also rejects connections if the load average is greater than 16.

As each command is received, `nnrpd` tries to change its `argv` array so that `ps(1)` prints the command being executed. To get a full display, the `-s` flag may be used with a long string as its argument, which is overwritten when the program changes its title.

On exit, `nnrpd` reports usage statistics through `syslog(3)`.

If the `-t` flag is used, all client commands and initial responses are traced by reporting them in `syslog`. This flag is set by `innd` under the control of the `ctlinnd(8)` `trace` command and is toggled upon receipt of a `SIGHUP`; see `signal(2)`.

If the `-s` flag is used, all postings are forwarded to the specified host, which should be the master NNTP server. This flag is set by `innd` if it is started with the `-s` flag.

`nnrpd` can accept multimedia postings that follow the MIME standard as long as such postings are also acceptable as SMTP messages. See the discussion of the MIME headers in `inn.conf(5)`.

PROTOCOL DIFFERENCES

`nnrpd` implements the NNTP commands defined in RFC 977 with the following differences:

- The `ihave` command is not implemented. Users should be using the `post` command to post articles.
- The `slave` command is not implemented. This command has never been fully defined.
- The `list` command may be followed by the optional word `active.times`, `distributions`, `distrib.pats`, `newsgroups`, or `overview.fmt` to get a list of when newsgroups were created, a list of valid distributions, a file specifying default distribution patterns, a one-per-line description of the current set of newsgroups, or a listing of the `overview.fmt(5)` file. The command `list active` is equivalent to the `list` command. This is a common extension.
- The `xhdr`, `authinfo user`, and `authinfo pass` commands are implemented. These are based on the reference UNIX implementation; no other documentation is available.
- A new command, `xpat header range|MessageID pat [morepat...]`, is provided. The first argument is the case-insensitive name of the header to be searched. The second argument is either an article range or a single Message-ID as specified in RFC 977. The third argument is a `wildmat(3)`-style pattern; if there are additional arguments, they are joined together separated by a single space to form the complete pattern. This command is similar to the `xhdr` command. It returns a 221 response code, followed by the text response of all article numbers that match the pattern.
- The `listgroup group` command is provided. This is a comment extension. It is equivalent to the `group` command, except that the reply is a multi-line response containing the list of all article numbers in the group.
- The `xgtitle [group]` command is provided. This extension is used by ANU-News. It returns a 282 reply code, followed by a one-line description of all newsgroups that match the pattern. The default is the current group.
- The `xover [range]` command is provided. It returns a 224 reply code, followed by the overview data for the specified range; the default is to return the data for the current article.
- The `xpath MessageID` command is provided; see `innd(8)`.
- The `date` command is provided; this is based on the draft NNTP protocol revision. It returns a one-line response code of 111 followed by the GMT date and time on the server in the form `YYYYMMDDhhmmss`.

nntpsend

nntpsend—Send Usenet articles to remote site.

SYNOPSIS

```
nntpsend [ -d ][ -p ][ -r ][ -S ][ -s size ][ -t timeout ]
[ -T timelimit ][ sitename fqdn ] ...
```

DESCRIPTION

nntpsend is a front end that invokes [innxmit\(1\)](#) to send Usenet articles to a remote NNTP site.

The sites to be fed may be specified by giving `si tename fqdn` pairs on the command line. If no such pairs are given, nntpsend defaults to the information given in the [nntpsend.ct1\(5\)](#) config file.

The `si tename` should be the name of the site as specified in the [newsfeeds\(5\)](#) file. The `fqdn` should be the hostname or IP address of the remote site. An [innxmit](#) is launched for sites with queued news. All [innxmit](#) processes are spawned in the background and the script waits for them all to finish before returning. Output is sent to the file `/var/log/news/nntpsend.log`. To avoid overwhelming the local system, nntpsend waits five seconds before spawning each child. The flag `-a` is always given as a flag to [innxmit](#).

nntpsend expects that the batchfile for a site is named `/news/spool/out.going/si tename`. To prevent batchfile corruption, [shlock\(1\)](#) is used to “lock” these files.

The `-p`, `-r`, `-s`, `-t`, and `-T` flags are passed on to the child [innxmit](#) program. Note that if the `-p` flag is used then no connection is made and no articles are fed to the remote site. It is useful to have [cron\(8\)](#) invoke nntpsend with this flag in case a site cannot be reached for an extended period of time.

If the `-s` flag is used, then [shrinkfile\(1\)](#) is invoked to perform a tail truncation on the batchfile and the flag is passed to it.

When `si tename fqdn` pairs are given on the command line, any flags given on the command completely describe how [innxmit](#) and [shrinkfile](#) operate. When no such pairs are given on the command line, then the information found in [nntpsend.ct1](#) becomes the default flags for that site. Any flags given on the command line override the default flags for the site.

For example, with the following control file:

```
nsavax:erehwon.nsavax.gov::-S -t60
group70:group70.org::
walldrug:walldrug.com:1m:-T1800 -t300
```

The command

```
nntpsend
```

will result in the following:

Sitename	Truncation	Innxmit flags
nsavax	(none)	-a -S -t60
group70	(none)	-a -t180
walldrug	1m	-a -T1800 -t300

The command

```
nntpsend -d -T1200
```

will result in the following:

Sitename	Truncation	Innxmit flags
nsavax	(none)	-a -d -S -T1200 -t60
group70	(none)	-a -d -T1200 -t180
walldrug	1m	-a -d -T1200 -t300

The command

```
nntpsend -s 5m -T1200 nsavax erehwon.nsavax.gov group70 group70.org
```

will result in the following:

Sitename	Truncation	Innxmit flags
nsavax	5m	-a -T1200 -t180
group70	5m	-a -T1200 -t180

Remember that `-a` is always given, and `-t` defaults to 180.

nslookup

`nslookup`—Query Internet nameservers interactively.

SYNOPSIS

```
nslookup [ -option ... ] [ host-to-find ] -[server ]
```

DESCRIPTION

`nslookup` is a program to query Internet domain nameservers. `nslookup` has two modes: interactive and non-interactive.

Interactive mode allows the user to query nameservers for information about various hosts and domains or to print a list of hosts in a domain. Non-interactive mode is used to print just the name and requested information for a host or domain.

ARGUMENTS

Interactive mode is entered in the following cases:

- When no arguments are given (the default nameserver is used)
- When the first argument is a hyphen (-) and the second argument is the hostname or Internet address of a nameserver

Non-interactive mode is used when the name or Internet address of the host to be looked up is given as the first argument. The optional second argument specifies the host name or address of a nameserver.

The options listed under the `set` command can be specified in the `.nslookupprc` file in the user's home directory if they are listed one per line. Options can also be specified on the command line if they precede the arguments and are prefixed with a hyphen. For example, to change the default query type to host information, and the initial timeout to 10 seconds, type:

```
nslookup -query=hinfo -timeout=10
```

INTERACTIVE COMMANDS

Commands may be interrupted at any time by typing Ctrl+C. To exit, type Ctrl+D (EOF) or type `exit`. The command-line length must be less than 256 characters. To treat a built-in command as a hostname, precede it with an escape character (`\`). Note that an unrecognized command is interpreted as a hostname.

<code>host [server]</code>	Look up information for <code>host</code> using the current default server or using <code>server</code> if specified. If <code>host</code> is an Internet address and the query type is <code>A</code> or <code>PTR</code> , the name of the host is returned. If <code>host</code> is a name and does not have a trailing period, the default domain name is appended to the name. (This behavior depends on the state of the set options <code>domain</code> , <code>srchlist</code> , <code>defname</code> , and <code>search</code>). To look up a host not in the current domain, append a period to the name.
<code>server domain, lserver domain</code>	Change the default server to <code>domain</code> . <code>lserver</code> uses the initial server to look up information about <code>domain</code> , whereas <code>server</code> uses the current default server. If an authoritative answer can't be found, the names of servers that might have the answer are returned.
<code>root</code>	Changes the default server to the server for the root of the domain name space. Currently, the host <code>ns.internic.net</code> is used. (This command is a synonym for <code>lserver ns.internic.net</code> .) The name of the root server can be changed with the <code>set root</code> command.
<code>finger [name][> filename], finger [name][>> filename]</code>	Connects with the finger server on the current host. The current host is defined when a previous lookup for a host was successful and returned address information (see the <code>set query-type= A</code> command). <code>name</code> is optional. <code>></code> and <code>>></code> can be used to redirect output in the usual manner.
<code>ls [option] domain [> filename], ls [option] domain [>> filename]</code>	List the information available for <code>domain</code> , optionally creating or appending to <code>filename</code> . The default output contains hostnames and their Internet addresses. <code>option</code> can be one of the following:
<code>-t querytype</code>	Lists all records of the specified type (see <code>querytype</code>).
<code>-a</code>	Lists aliases of hosts in the domain. Synonym for <code>-t CNAME</code> .
<code>-d</code>	Lists all records for the domain. Synonym for <code>-t ANY</code> .
<code>-h</code>	Lists CPU and operating system information for the domain. Synonym for <code>-t HINFO</code> .
<code>-s</code>	Lists well-known services of hosts in the domain. Synonym for <code>-t WKS</code> . When output is directed to a file, hash marks are printed for every 50 records received from the server.
<code>view filename</code>	Sorts and lists the output of previous <code>ls</code> commands with <code>more(1)</code> .
<code>help, ?</code>	Prints a brief summary of commands.
<code>exit</code>	Exits the program.
<code>set keyword[=value]</code>	This command is used to change state information that affects the lookups. Valid keywords are:
<code>all</code>	Prints the current values of the frequently used options to <code>set</code> . Information about the current default server and host is also printed.
<code>class=value</code>	Change the query class to one of the following:
<code>IN</code>	The Internet class.
<code>CHAOS</code>	The Chaos class.

	HESIOD	The MIT Athena Hesiod class.
	ANY	Wildcard (any of the above).
		The class specifies the protocol group of the information. (Default = IN, abbreviation = cl.)
[no]debug		Turn debugging mode on. A lot more information is printed about the packet sent to the server and the resulting answer. (Default = nodebug, abbreviation = [no]deb.)
[no]d2		Turn exhaustive debugging mode on. Essentially, all fields of every packet are printed. (Default = nod2.)
domain=name		Change the default domain name to <i>name</i> . The default domain name is appended to a lookup request depending on the state of the <i>defname</i> and <i>search</i> options. The domain search list contains the parents of the default domain if it has at least two components in its name. For example, if the default domain is CC.Berkeley.EDU, the search list is CC.Berkeley.EDU and Berkeley.EDU. Use the <i>set srchlist</i> command to specify a different list. Use the <i>set all</i> command to display the list. (Default = value from <i>hostname</i> , <i>/etc/resolv.conf</i> , or LOCALDO-MAIN, abbreviation = do.)
srchlist=name1/name2/...		Change the default domain name to <i>name1</i> and the domain search list to <i>name1</i> , <i>name2</i> , and so on. A maximum of six names separated by slashes (/) can be specified. For example, <i>set srchlist=1cs.MIT.EDU/ai.MIT.EDU/MIT.EDU</i> sets the domain to 1cs.MIT.EDU and the search list to the three names. This command overrides the default domain name and search list of the <i>set domain</i> command. Use the <i>set all</i> command to display the list. (Default = value based on <i>hostname</i> , <i>/etc/resolv.conf</i> , or LOCAL-DOMAIN, abbreviation = srchl.)
[no]defname		If set, append the default domain name to a single-component lookup request (that is, one that does not contain a period). (Default = <i>defname</i> , abbreviation = [no]def.)
[no]search		If the lookup request contains at least one period but doesn't end with a trailing period, append the domain names in the domain search list to the request until an answer is received. (Default = <i>search</i> , abbreviation = [no]sea.)
port=val ue		Change the default TCP/UDP nameserver port to <i>val ue</i> . (Default = 53, abbreviation = po.)
querytype=val ue, type=val ue		Change the type of information query to one of the following:
	A	The host's Internet address.
	CNAME	The canonical name for an alias.
	HINFO	The host CPU and operating system type.
	MINFO	The mailbox or mail list information.
	MX	The mail exchanger.
	NS	The nameserver for the named zone.
	PTR	The host name if the query is an Internet address; otherwise, the pointer to other information.
	SOA	The domain's "start-of-authority" information.
	TXT	The text information.
	UINFO	The user information.
	WKS	The supported well-known services.
		Other types (ANY, AXFR, MB, MD, MF, NULL) are described in the RFC-1035 document. (Default = A, abbreviations = q, ty.)
[no]recurse		Tell the nameserver to query other servers if it does not have the information. (Default = recurse, abbreviation = [no]rec.)
retry=number		Set the number of retries to <i>number</i> . When a reply to a request is not received within a certain amount of time (changed with <i>set timeout</i>), the timeout period is doubled and the request is resent. The <i>retry</i> value controls how many times a request is resent before giving up. (Default = 4, abbreviation = ret.)

root=host	Change the name of the root server to <code>host</code> . This affects the <code>root</code> command. (Default = <code>ns.internic.net</code> , abbreviation = <code>ro</code> .)
timeout=number	Change the initial timeout interval for waiting for a reply to <code>number</code> seconds. Each retry doubles the timeout period. (Default = 5 seconds, abbreviation = <code>ti</code> .)
[no]vc	Always use a virtual circuit when sending requests to the server. (Default = <code>novc</code> , abbreviation = <code>[no]v</code> .)
[no]ignoretc	Ignore packet truncation errors. (Default = <code>noignoretc</code> , abbreviation = <code>[no]ig</code> .)

DIAGNOSTICS

If the lookup request was not successful, an error message is printed. Possible errors are

Timed out	The server did not respond to a request after a certain amount of time (changed with <code>set timeout=value</code>) and a certain number of retries (changed with <code>set retry=value</code>).
No response from server	No nameserver is running on the server machine.
No records	The server does not have resource records of the current query type for the host, although the hostname is valid. The query type is specified with the <code>set querytype</code> command.
Non-existent domain	The host or domain name does not exist.
Connection refused, Network is unreachable	The connection to the name or finger server could not be made at the current time. This error commonly occurs with <code>ls</code> and <code>finger</code> requests.
Server failure	The nameserver found an internal inconsistency in its database and could not return a valid answer.
Refused	The nameserver refused to service the request.
Format error	The nameserver found that the request packet was not in the proper format. It may indicate an error in <code>nslookup</code> .

FILES

<code>/Etc/Resolv.conf</code>	Initial domain name and nameserver addresses.
<code>\$HOME/.nslookuprc</code>	User's initial options.
<code>/usr/share/misc/nslookup.help</code>	Summary of commands.

ENVIRONMENT

<code>HOSTALIASES</code>	File containing host aliases.
<code>LOCALDOMAIN</code>	Overrides default domain.

overchan

overchan—Update the news overview database.

SYNOPSIS

```
overchan [ -D dir ][-c ][file... ]
```

DESCRIPTION

`overchan` reads article data from files or standard input if none are specified. (A single dash in the file list means to read standard input.) It uses this information to update the news overview database. `overchan` is designed to be used by InterNetNews or the C News `mkov` packages to update the database as the articles come in. The database for each newsgroup is stored in a file named `.overview` in a newsgroup directory within the overview database tree.

`overchan` locks the database file (by locking an auxiliary file) before appending the new data. To purge data after articles have been expired, see `expireover(8)`.

By default, `overchan` processes its input as an INN overview stream written as a `WO` entry in the `newsfeeds(5)` file:

```
overview:*:Tc,W0:/news/bin/overchan
```

This data consists of a line of text separated into two parts by a tab. The first part is a list of all relative pathnames where the article has been written with a single space between entries. The second part is the data to be written into the overview file, except that the initial article number is omitted.

To process the output of the `mkov(8)` program, use the `-c` flag. This format is described in the `nov` distribution.

The `-D` flag can be used to specify where the databases are stored. The default directory is `/news/spool`.

HISTORY

pac

`pac`—Printer/plotter accounting information.

SYNOPSIS

```
pac [-P printer] [-c] [-m] [-p price] [-s] [-r] [name ...]
```

DESCRIPTION

`pac` reads the printer/plotter accounting files, accumulating the number of pages (the usual case) or feet (for raster devices) of paper consumed by each user and printing how much each user consumed in pages or feet and dollars.

Options and operands available:

- `-P printer` Accounting is done for the named printer. Usually, accounting is done for the default printer (site dependent), or the value of the environment variable `PRINTER` is used.
- `-c` Flag causes the output to be sorted by cost; usually, the output is sorted alphabetically by name.
- `-m` Flag causes the hostname to be ignored in the accounting file. This allows for a user on multiple machines to have all his printing charges grouped together.
- `-p price` The value `price` is used for the cost in dollars instead of the default value of 0.02 or the price specified in `/etc/printcap`.
- `-r` Reverse the sorting order.
- `-s` Accounting information is summarized on the summary accounting file; this summarization is necessary because on a busy system, the accounting file can grow by several lines per day.

names Statistics are only printed for users named; usually, statistics are printed for every user who has used any paper.

FILES

<code>/var/account/?acct</code>	Raw accounting files
<code>/var/account/?_sum</code>	Summary accounting files
<code>/etc/printcap</code>	Printer capability database

SEE ALSO

`printcap(5)`

BUGS

The relationship between the computed price and reality is as yet unknown.

HISTORY

The `pac` command appeared in BSD 4.0.

BSD 4.2, 16 March 1991

pcnfsd

pcnfsd—(PC)NFS authentication and print request server

SYNOPSIS

`/usr/etc/rpc.pcnfsd`

AVAILABILITY

This program is freely redistributable.

DESCRIPTION

`pcnfsd` is an RPC server that supports ONC clients on PC (DOS, OS/2, Macintosh, and other) systems. This page describes version 2 of the `pcnfsd` server.

`rpc.pcnfsd` may be started from `/etc/rc.local` or by the `inetd(8)` superdaemon. It reads the configuration file `/etc/pcnfsd.conf` if present and then services RPC requests directed to program number 150001. This release of the `pcnfsd` daemon supports both version 1 and version 2 of the `pcnfsd` protocol. Consult the `rpcgen` source file `pcnfsd.x` for details of the protocols.

The requests serviced by `pcnfsd` fall into three categories: authentication, printing, and other. Only the authentication and printing services have administrative significance.

AUTHENTICATION

When `pcnfsd` receives a `PCNFSD AUTH` or `PCNFSD2 AUTH` request, it “logs in” the user by validating the username and password and returning the corresponding UID, GIDs, home directory, and `umask`. If `pcnfsd` was built with the `WTMP` compile-time option, it also appends a record to the `wtmp(5)` database. If you do not want to record PC logins in this way, you should add a line of the form

```
wtmp off
```

to the `/etc/pcnfsd.conf` file.

By default, `pcnfsd` only allows authentication or print requests for users with UIDs in the range 101 to 60002. (This corresponds in `SVR4` to the range for non-system accounts.) To override this, you may add a line of the form

`uidrange range[,range]...`

to the `/etc/pcnfsd.conf` file. Here, each `range` is of the form `ui d` or `ui d-ui d`, indicating an inclusive range.

PRINTING

`pcnfsd` supports a printing model based on the use of NFS to transfer the actual print data from the client to the server. The client system issues a `PCNFSD_PR_INIT` or `PCN-FSD2_PR_INIT` request, and the server returns the path to a spool directory that the client may use and which is exported by NFS. `pcnfsd` creates a subdirectory for each of its clients: The parent directory is usually `/usr/spool/pcnfs` and the subdirectory is the hostname of the client system. If you want to use a different parent directory, you should add a line of the form

```
spooldir path
```

to the `/etc/pcnfsd.conf` file.

Once a client has mounted the spool directory using NFS and has transferred print data to a file in this directory, it issues a `PCNFSD_PR_START` or `PCNFSD2_PR_START` request. `pcnfsd` handles this, and most other print-related requests, by constructing a command based on the printing services of the server operating system and executing the command using the identity of the PC user. Because this involves set-user-ID privileges, `pcnfsd` must be run as root.

Every print request from the client includes the name of the printer that is to be used. In Linux, this name corresponds to a printer definition in the `/etc/printcap(5)` database. If you want to define a non-standard way of processing print data, you should define a new printer and arrange for the client to print to this printer. There are two ways of setting up a new printer. The first involves the addition of an entry to `/etc/printcap(5)` and the creation of filters to perform the required processing. This is outside the scope of this discussion. In addition, `pcnfsd` includes a mechanism by which you can define virtual printers known only to `pcnfsd` clients. Each printer is defined by a line in the `/etc/pcnfsd.conf` file of the following form:

```
printer name alias-for command
```

`name` is the name of the printer you want to define. `alias-for` is the name of a “real” printer that corresponds to this printer. For example, a request to display the queue for `name` is translated into the corresponding request for the printer `alias-for`. If you have defined a printer in such a way that there is no “real” printer to which it corresponds, use a single `.` for this field. (See the definition of the printer `test` for an example.) `command` is a command that will be executed whenever a file is printed on `name`. This command is executed by the shell at `/bin/sh` using the `-c` option. For complex operations, you should construct an executable shell program and invoke that in `command`.

Consider the following sample `/etc/pcnfsd.conf` file:

```
printer rotated lw /usr/local/bin/enscript -2r $FILE
printer test . /usr/bin/cp $FILE/usr/tmp/$HOST$USER
```

If a client system prints a job on the printer `rotated`, the utility `enscript` is invoked to pre-process the file `$FILE`. In this case, the `-2r` option causes the file to be printed in two-column `rotated` format on the default PostScript printer. If the client requests a list of the print queue for the printer `rotated`, the `pcnfsd` daemon translates this into a request for a listing for the printer `lw`.

The printer `test` is used only for testing. Any file sent to this printer is copied into `/usr/tmp`. Any request to list the queue, check the status, and so on of printer `test` is rejected because the `alias-for` is specified as `.`.

RECONFIGURATION

pcnfsd detects when printers are added or deleted and rebuilds its list of valid printers. To do this, it checks the modification time of `/etc/printcap`. However, it does not monitor the file `/etc/pcnfsd.conf` for updates; if you change this file, it is still necessary to kill and restart `pcnfsd` so the changes can take effect.

plipconfig

plipconfig—Fine-tune PLIP device parameters.

SYNOPSIS

```
plipconfig interface
plipconfig interface [nibble NN] [trigger NN] [unit NN]
```

DESCRIPTION

`plipconfig` is used to improve PLIP performance by changing the default timing parameters used by the PLIP protocol. Results are dependent on the parallel port hardware, cable, and the CPU speed of each machine on each end of the PLIP link.

If the single `interface` argument is given, `plipconfig` displays the status of the given interface only. Otherwise, it tries to set the options.

OPTIONS

<code>nibble NN</code>	Sets the nibble wait value in microseconds. Default is 3000.
<code>trigger NN</code>	Sets the trigger wait value in microseconds. Default is 500.
<code>unit NN</code>	Sets the number of units of delay. Default is 1.

In some cases, PLIP speed can be improved by lowering the default values. Values that are too low might cause excess use of CPU, poor interrupt response time resulting in serial ports dropping characters, or in dropping PLIP packets. Changing the `plip` MTU can also affect PLIP speed.

SEE ALSO

`ifconfig(8)`

BUGS

None so far.

ping

ping—Send ICMP ECHO_REQUEST packets to network hosts.

SYNOPSIS

```
/etc/ping [ -r ][ -v ] host [ packetsize ][count ]
```

DESCRIPTION

The DARPA Internet is a large and complex aggregation of network hardware, connected together by gateways. Tracking a single-point hardware or software failure can often be difficult. Ping utilizes the ICMP protocol's mandatory ECHO_REQUEST datagram to elicit an ICMP ECHO_RESPONSE from a host or gateway. ECHO_REQUEST datagrams ("pings") have an IP and ICMP header, followed by a struct timeval and then an arbitrary number of "pad" bytes used to fill out the packet. Default datagram length is 64 bytes, but this may be changed using the command-line option. Other options are

- r Bypass the normal routing tables and send directly to a host on an attached network. If the host is not on a directly attached network, an error is returned. This option can be used to ping a local host through an interface that has no route through it (for example, after the interface was dropped by routed(8C)).
- v Verbose output. ICMP packets other than ECHO_RESPONSE that are received are listed.

When using ping for fault isolation, it should first be run on the local host to verify that the local network interface is up and running. Then, hosts and gateways further away should be pinged. Ping sends one datagram per second and prints one line of output for every ECHO_RESPONSE returned. No output is produced if there is no response. If an optional count is given, only that number of requests is sent. Round-trip times and packet-loss statistics are computed. When all responses have been received or the program times out (with a count specified), or if the program is terminated with a SIGINT, a brief summary is displayed.

This program is intended for use in network testing, measurement, and management. It should be used primarily for manual fault isolation. Because of the load it could impose on the network, it is unwise to use ping during normal operations or from automated scripts.

portmap

portmap—DARPA port to RPC program number mapper.

SYNOPSIS

```
portmap [-d]
```

DESCRIPTION

portmap is a server that converts RPC program numbers into DARPA protocol port numbers. It must be running in order to make RPC calls.

When an RPC server is started, it tells portmap what port number it is listening to and what RPC program numbers it is prepared to serve. When a client wants to make an RPC call to a given program number, it first contacts portmap on the server machine to determine the port number where RPC packets should be sent.

portmap must be started before any RPC servers are invoked.

Usually, portmap forks and dissociates itself from the terminal like any other daemon. Portmap then logs errors using syslog(3).

Option available:

-d (debug) prevents portmap from running as a daemon and causes errors and debugging information to be printed to the standard error output.

SEE ALSO

inetd.conf(5), rpcinfo(8), inetd(8)

BUGS

If portmap crashes, all servers must be restarted.

HISTORY

The portmap command appeared in BSD 4.3.

BSD 4.3, 16 March 1991

powerd

powerd—Monitor a serial line connected to a UPS.

SYNOPSIS

```
/etc/powerd serial -device
```

DESCRIPTION

powerd is a daemon process that sits in the background and monitors the state of the DCD line of the serial device. It is meant that this line is connected to a UPS (Uninterruptible Power Supply) so that it knows about the state of the UPS. As soon as powerd senses that the power is failing (it sees that DCD goes low) it notifies init(8) and init executes the powerwait and powerfail entries. If powerd senses that the power has been restored, it notifies init again and init executes the powerokwait entries.

ARGUMENTS

serial -device

Some serial port that is not being used by some other device and does not share an interrupt with any other serial port.

DIAGNOSTICS

powerd regularly checks the DSR line to see if it's high. DSR should be directly connected to DTR and powerd keeps that line high, so if DSR is low, something is wrong with the connection. powerd notifies you about this fact every two minutes. When it sees that the connection is restored, it will say so.

IMPLEMENTATION

It's pretty simple to connect your UPS to the Linux machine. The steps are easy:

1. Make sure you have an UPS with a simple relays output: it should close its connections (make) if the power is gone, and it should open its connections (break) if the power is good.
2. Buy a serial plug. Connect the DTR line to the DSR line directly. Connect the DTR line and the DCD line with a 10 kilo ohm resistor. Connect the relays-output of the UPS to GROUND and the DCD line. If you don't know what pins DSR, DTR, DCD and GROUND are, you can always ask at the store where you bought the plug.
3. You're all set.

BUGS

Well, it's not a real bug but `powerd` should be able to do a broadcast or something on the Ethernet in case more Linux-boxes are connected to the same UPS and only one of them is connected to the UPS status line.

pppd

pppd—Point-to-Point Protocol daemon.

SYNOPSIS

```
pppd [ tty_name ][speed ][options ]
```

DESCRIPTION

The Point-to-Point Protocol (PPP) provides a method for transmitting datagrams over serial point-to-point links. PPP is composed of three parts: a method for encapsulating datagrams over serial links, an extensible Link Control Protocol (LCP), and a family of Network Control Protocols (NCP) for establishing and configuring different network-layer protocols.

The encapsulation scheme is provided by driver code in the kernel. `pppd` provides the basic LCP, authentication support, and an NCP for establishing and configuring the Internet Protocol (IP) (called the IP Control Protocol, IPCP).

FREQUENTLY USED OPTIONS

<code>tty_name</code>	Communicate over the named device. The string <code>/dev/</code> is prepended if necessary. If no device name is given, or if the name of the controlling terminal is given, <code>pppd</code> uses the controlling terminal and does not fork to put itself in the background.
<code>speed</code>	Set the baud rate to <code>speed</code> (a decimal number). On systems such as 4.4BSD and NetBSD, any speed can be specified. Other systems (such as SunOS) allow only a limited set of speeds.
<code>asyncmap map</code>	Set the async character map to <code>map</code> . This map describes which control characters cannot be successfully received over the serial line. <code>pppd</code> asks the peer to send these characters as a 2-byte escape sequence. The argument is a 32-bit hex number with each bit representing a character to escape. Bit 0 (<code>00000001</code>) represents the character <code>0x00</code> ; bit 31 (<code>80000000</code>) represents the character <code>0x1f</code> or <code>^</code> . If multiple <code>asyncmap</code> options are given, the values are ORed together. If no <code>asyncmap</code> option is given, no async character map is negotiated for the receive direction; the peer should then escape all control characters.
<code>auth</code>	Require the peer to authenticate itself before allowing network packets to be sent or received.
<code>connect p</code>	Use the executable or shell command specified by <code>p</code> to set up the serial line. This script typically uses the <code>chat(8)</code> program to dial the modem and start the remote PPP session.
<code>crtcts</code>	Use hardware flow control (that is, RTS/CTS) to control the flow of data on the serial port. If neither the <code>crtcts</code> nor the <code>-crtcts</code> option is given, the hardware flow control setting for the serial port is left unchanged.
<code>defaultroute</code>	Add a default route to the system routing tables, using the peer as the gateway, when IPCP negotiation is successfully completed. This entry is removed when the PPP connection is broken.

<code>disconnect p</code>	Run the executable or shell command specified by <code>p</code> after <code>pppd</code> has terminated the link. This script could, for example, issue commands to the modem to cause it to hang up if hardware modem control signals were not available.
<code>escape xx,yy,...</code>	Specifies that certain characters should be escaped on transmission (regardless of whether the peer requests them to be escaped with its <code>asynctest</code> control character map). The characters to be escaped are specified as a list of hex numbers separated by commas. Note that almost any character can be specified for the <code>escape</code> option, unlike the <code>asynctest</code> option, which only allows control characters to be specified. The characters that cannot be escaped are those with hex values <code>0x20</code> - <code>0x3f</code> or <code>0x5e</code> .
<code>file f</code>	Read options from file <code>f</code> (the format is described later).
<code>lock</code>	Specifies that <code>pppd</code> should create a UUCP-style lock file for the serial device to ensure exclusive access to the device.
<code>mrui n</code>	Set the MRU (Maximum Receive Unit) value to <code>n</code> for negotiation. <code>pppd</code> asks the peer to send packets of no more than <code>n</code> bytes. The minimum MRU value is 128. The default MRU value is 1500. A value of 296 is recommended for slow links (40 bytes for TCP/IP header plus 256 bytes of data).
<code>mtu n</code>	Set the MTU (Maximum Transmit Unit) value to <code>n</code> . Unless the peer requests a smaller value via MRU negotiation, <code>pppd</code> requests that the kernel networking code send data packets of no more than <code>n</code> bytes through the PPP network interface.
<code>netmask n</code>	Set the interface netmask to <code>n</code> , a 32-bit netmask in decimal dot notation (such as 255.255.255.0). If this option is given, the value specified is <code>ored</code> with the default netmask. The default netmask is chosen based on the negotiated remote IP address; it is the appropriate network mask for the class of the remote IP address <code>ored</code> with the netmasks for any non-point-to-point network interfaces in the system that are on the same network.
<code>passive</code>	Enables the <code>passive</code> option in the LCP. With this option, <code>pppd</code> attempts to initiate a connection; if no reply is received from the peer, <code>pppd</code> then waits passively for a valid LCP packet from the peer (instead of exiting as it does without this option).
<code>silent</code>	With this option, <code>pppd</code> does not transmit LCP packets to initiate a connection until a valid LCP packet is received from the peer (as for the <code>passive</code> option with ancient versions of <code>pppd</code>).

OPTIONS

<code>local IP address:remote IP address</code>	Set the local and/or remote interface IP addresses. Either one may be omitted. The IP addresses can be specified with a host name or in decimal dot notation (such as 150.234.56.78). The default local address is the (first) IP address of the system (unless the <code>noipdefault</code> option is given). The remote address is obtained from the peer if not specified in any option. Thus, in simple cases, this option is not required. If a local and/or remote IP address is specified with this option, <code>pppd</code> does not accept a different value from the peer in the IPCP negotiation, unless the <code>ipcp-accept-local</code> and/or <code>ipcp-accept-remote</code> options are given.
<code>-ac</code>	Disable Address/Control compression negotiation (use default, address/control field compression disabled).
<code>-all</code>	Don't request or allow negotiation of any options for LCP and IPCP (use default values).
<code>-am</code>	Disable <code>asynctest</code> negotiation (use the default <code>asynctest</code> ; that is, escape all control characters).
<code>-as n</code>	Same as <code>asynctest n</code> .

<code>bsdcomp nr,nt</code>	Request that the peer compress packets that it sends, using the BSD-Compress scheme, with a maximum code size of <code>nr</code> bits and agree to compress packets sent to the peer with a maximum code size of <code>nt</code> bits. If <code>nt</code> is not specified, it defaults to the value given for <code>nr</code> . Values in the range 9 to 15 may be used for <code>nr</code> and <code>nt</code> ; larger values give better compression but consume more kernel memory for compression dictionaries. Alternatively, a value of 0 for <code>nr</code> or <code>nt</code> disables compression in the corresponding direction.
<code>-bsdcomp</code>	Disables compression; <code>pppd</code> does not request or agree to compress packets using the BSD-Compress scheme.
<code>+chap</code>	Require the peer to authenticate itself using CHAP (Cryptographic Handshake Authentication Protocol) authentication.
<code>-chap</code>	Don't agree to authenticate using CHAP.
<code>chap-interval n</code>	If this option is given, <code>pppd</code> rechallenges the peer every <code>n</code> seconds.
<code>chap-max-challenge n</code>	Set the maximum number of CHAP challenge transmissions to <code>u</code> (default is 10).
<code>chap-restart n</code>	Set the CHAP restart interval (retransmission timeout for challenges) to <code>n</code> seconds (default is 3).
<code>-crtsets</code>	Disable hardware flow control (RTS/CTS) on the serial port. If neither the <code>crtsets</code> nor the <code>-crtsets</code> option is given, the hardware flow control setting for the serial port is left unchanged.
<code>-d</code>	Increase debugging level (same as the <code>debug</code> option).
<code>debug</code>	Increase debugging level (same as <code>-d</code>). If this option is given, <code>pppd</code> logs the contents of all control packets sent or received in a readable form. The packets are logged through <code>syslog</code> with facility <code>daemon</code> and level <code>debug</code> . This information can be directed to a file by setting up <code>/etc/syslog.conf</code> appropriately (see <code>syslog.conf(5)</code>).
<code>-defaultroute</code>	Disable the <code>defaultroute</code> option. The system administrator who wants to prevent users from creating default routes with <code>pppd</code> can do so by placing this option in the <code>/etc/ppp/options</code> file.
<code>-detach</code>	Don't fork to become a background process (otherwise, <code>pppd</code> will do so if a serial device other than its controlling terminal is specified).
<code>dns-addr n</code>	This option sets the IP address or addresses for the Domain Name Server. It is used by Microsoft Windows clients. The primary DNS address is specified by the first instance of the <code>dns-addr</code> option. The secondary is specified by the second instance.
<code>domain d</code>	Append the domain name <code>d</code> to the local hostname for authentication purposes. For example, if <code>gethost-name()</code> returns the name <code>porsche</code> , but the fully qualified domain name is <code>porsche.Quotron.COM</code> , you use the <code>domain</code> option to set the domain name to <code>Quotron.COM</code> .
<code>-ip</code>	Disable IP address negotiation. If this option is used, the remote IP address must be specified with an option on the command line or in an options file.
<code>+ip-protocol</code>	Enable the IPCP and IP protocols. This is the default condition. This option is only needed if the default setting is <code>-ip-protocol</code> .
<code>-ip-protocol</code>	Disable the IPCP and IP protocols. This should only be used if you know you are using a client that only understands IPX and you don't want to confuse the client with the IPCP protocol.
<code>+ipx-protocol</code>	Enable the IPXCP and IPX protocols. This is the default condition if your kernel supports IPX. This option is only needed if the default setting is <code>-ipx-protocol</code> . If your kernel does not support IPX, this option has no effect.

<code>-ipx-protocol</code>	Disable the IPXCP and IPX protocols. This should only be used if you know you are using a client that only understands IP and you don't want to confuse the client with the IPXCP protocol.
<code>ipcp-accept-local</code>	With this option, <code>pppd</code> accepts the peer's idea of a local IP address, even if the local IP address was specified in an option.
<code>ipcp-accept-remote</code>	With this option, <code>pppd</code> accepts the peer's idea of its (remote) IP address, even if the remote IP address was specified in an option.
<code>ipcp-max-configure n</code>	Set the maximum number of IPCP configure-request transmissions to <code>n</code> (default is 10).
<code>ipcp-max-failure n</code>	Set the maximum number of IPCP configure-NAKs returned before starting to send configure-Rejects instead to <code>n</code> (default is 10).
<code>ipcp-max-terminate n</code>	Set the maximum number of IPCP terminate-request transmissions to <code>n</code> (default is 3).
<code>ipcp-restart n</code>	Set the IPCP restart interval (retransmission timeout) to <code>n</code> seconds (default is 3).
<code>ipparam string</code>	Provides an extra parameter to the <code>ip-up</code> and <code>ip-down</code> scripts. If this option is given, the <code>string</code> supplied is given as the sixth parameter to those scripts.
<code>ipx-network n</code>	Set the IPX network number in the IPXCP configure request frame to <code>n</code> . There is no valid default. If this option is not specified, the network number is obtained from the peer. If the peer does not have the network number, the IPX protocol is not started. This is a hexadecimal number and is entered without any leading sequence such as <code>0x</code> . It is related to the <code>ipxcp-accept-network</code> option.
<code>ipx-node n:m</code>	Set the IPX node numbers. The two node numbers are separated from each other with a colon character. The first number <code>n</code> is the local node number. The second number <code>m</code> is the peer's node number. Each node number is a hexadecimal number to the maximum of ten significant digits. The node numbers on the <code>ipx-network</code> must be unique. There is no valid default. If this option is not specified, the node number is obtained from the peer. This option is a related to the <code>ipxcp-accept-local</code> and <code>ipxcp-accept-remote</code> options.
<code>ipx-router-name string</code>	Set the name of the router. This is a string and is sent to the peer as information data.
<code>ipx-routing n</code>	Set the routing protocol to be received by this option. More than one instance of <code>ipx-routing</code> may be specified. The <code>none</code> option (<code>0</code>) may be specified as the only instance of <code>ipx-routing</code> . The values are <code>0</code> for none, <code>2</code> for RIP/SAP, and <code>4</code> for NLSP.
<code>ipxcp-accept-local</code>	Accept the peer's NAK for the node number specified in the <code>ipx-node</code> option. If a node number was specified and it is nonzero, the default is to insist that the value be used. If you include this option, you permit the peer to override the entry of the node number.
<code>ipxcp-accept-network</code>	Accept the peer's NAK for the network number specified in the <code>ipx-network</code> option. If a network number was specified and it is nonzero, the default is to insist that the value be used. If you include this option, you permit the peer to override the entry of the node number.
<code>ipxcp-accept-remote</code>	Use the peer's network number specified in the configure request frame. If a node number was specified for the peer and this option was not specified, the peer is forced to use the value that you specified.
<code>ipxcp-max-configure n</code>	Set the maximum number of IPXCP configure request frames that the system sends to <code>n</code> . The default is 10.

<code>ipxcp-max-failure n</code>	Set the maximum number of IPXCP NAK frames that the local system sends before it rejects the options. The default value is 3.
<code>ipxcp-max-terminate n</code>	Set the maximum number of IPXCP terminate request frames before the local system considers that the peer is not listening to them. The default value is 3.
<code>kdebug n</code>	Enable debugging code in the kernel-level PPP driver. The argument <code>n</code> is a number that is the sum of the following values: 1 to enable general debug messages, 2 to request that the contents of received packets be printed, and 4 to request that the contents of transmitted packets be printed.
<code>lcp-echo-failure n</code>	If this option is given, <code>pppd</code> presumes the peer is dead if <code>n</code> LCP echo-requests are sent without receiving a valid LCP echo-reply. If this happens, <code>pppd</code> terminates the connection. Use of this option requires a nonzero value for the <code>lcp-echo-interval</code> parameter. This option can be used to enable <code>pppd</code> to terminate after the physical connection has been broken (for example, the modem has hung up) in situations where no hardware modem control lines are available.
<code>lcp-echo-interval n</code>	If this option is given, <code>pppd</code> sends an LCP echo-request frame to the peer every <code>n</code> seconds. Under Linux, the echo-request is sent when no packets are received from the peer for <code>n</code> seconds. Usually, the peer should respond to the echo-request by sending an echo-reply. This option can be used with the <code>lcp-echo-failure</code> option to detect that the peer is no longer connected.
<code>lcp-max-configure n</code>	Set the maximum number of LCP configure-request transmissions to <code>n</code> (default is 10).
<code>lcp-max-failure n</code>	Set the maximum number of LCP configure-NAKs returned before starting to send configure-Rejects instead to <code>n</code> (default is 10).
<code>lcp-max-terminate n</code>	Set the maximum number of LCP terminate-request transmissions to <code>n</code> (default is 3).
<code>lcp-restart n</code>	Set the LCP restart interval (retransmission timeout) to <code>n</code> seconds (default is 3).
<code>local</code>	Don't use the modem control lines. With this option, <code>pppd</code> ignores the state of the CD (Carrier Detect) signal from the modem and does not change the state of the DTR (Data Terminal Ready) signal.
<code>login</code>	Use the system password database for authenticating the peer using PAP, and record the user in the system <code>wtmp</code> file.
<code>modem</code>	Use the modem control lines. This option is the default. With this option, <code>pppd</code> waits for the CD (Carrier Detect) signal from the modem to be asserted when opening the serial device (unless a connect script is specified), and it drops the DTR (Data Terminal Ready) signal briefly when the connection is terminated and before executing the connect script. On Ultrix, this option implies hardware flow control, as for the <code>crtsets</code> option.
<code>-mn</code>	Disable magic number negotiation. With this option, <code>pppd</code> cannot detect a looped-back line.
<code>-mru</code>	Disable MRU (MaximumReceive Unit) negotiation. With this option, <code>pppd</code> uses the default MRU value of 1500 bytes.
<code>name n</code>	Set the name of the local system for authentication purposes to <code>n</code> .
<code>noipdefault</code>	Disables the default behavior when no local IP address is specified, which is to determine (if possible) the local IP address from the hostname. With this option, the peer must supply the local IP address during IPCP

	negotiation (unless it specified explicitly on the command line or in an options file).
-p	Same as the <code>passive</code> option.
+pap	Require the peer to authenticate itself using PAP.
-pap	Don't agree to authenticate using PAP.
papcrypt	Indicates that all secrets in the <code>/etc/ppp/pap-secrets</code> file, which are used for checking the identity of the peer, are encrypted, and thus <code>pppd</code> should not accept a password (before encryption) that is identical to the secret from the <code>/etc/ppp/pap-secrets</code> file.
pap-max-authreq n	Set the maximum number of PAP authenticate-request transmissions to <code>n</code> (default is 10).
pap-restart n	Set the PAP restart interval (retransmission timeout) to <code>n</code> seconds (default is 3).
pap-timeout n	Set the maximum time that <code>pppd</code> waits for the peer to authenticate itself with PAP to <code>n</code> seconds (0 means no limit).
-pc	Disable protocol field compression negotiation (use default, protocol field compression disabled).
persist	Do not exit after a connection is terminated; instead, try to reopen the connection.
pred1comp	Attempt to request that the peer send the local system frames, which have been compressed by the Predictor-1 compression. The compression protocols must be loaded or this option is ignored.
-pred1comp	Do not accept Predictor-1 compression, even if the peer wants to send this type of compression and support has been defined in the kernel.
proxyarp	Add an entry to this system's ARP (Address Resolution Protocol) table with the IP address of the peer and the Ethernet address of this system.
-proxyarp	Disable the <code>proxyarp</code> option. The system administrator who wants to prevent users from creating proxy ARP entries with <code>pppd</code> can do so by placing this option in the <code>/etc/ppp/options</code> file.
remotename n	Set the assumed name of the remote system for authentication purposes to <code>n</code> .
+ua p	Agree to authenticate using PAP (Password Authentication Protocol) if requested by the peer and use the data in file <code>p</code> for the user and password to send to the peer. The file contains the remote username, followed by a newline, followed by the remote password, followed by a newline. This option is obsolescent.
usehostname	Enforce the use of the hostname as the name of the local system for authentication purposes (overrides the <code>name</code> option).
user u	Set the username to use for authenticating this machine with the peer using PAP to <code>u</code> .
-vj	Disable negotiation of Van Jacobson-style TCP/IP header compression (use default, no compression).
-vjccomp	Disable the connection-ID compression option in Van Jacobson style TCP/IP header compression. With this option, <code>pppd</code> does not omit the connection-ID byte from Van Jacobson compressed TCP/IP headers or ask the peer to do so.
vj-max-slots n	Sets the number of connection slots to be used by the Van Jacobson TCP/IP header compression and decompression code to <code>n</code> , which must be between 2 and 16 (inclusive).

xonxoff

Use software flow control (XON/XOFF) to control the flow of data on the serial port. This option is only implemented on Linux systems at present.

OPTIONS FILES

Options can be taken from files as well as the command line. `pppd` reads options from the files `/etc/ppp/options` and `~/ppp` before looking at the command line. An options file is parsed into a series of words, delimited by whitespace. Whitespace can be included in a word by enclosing the word in quotes (`"`). A backslash (`\`) quotes the following character. A hash (`#`) starts a comment, which continues until the end of the line.

AUTHENTICATION

`pppd` provides system administrators with sufficient access control so that PPP access to a server machine can be provided to legitimate users without fear of compromising the security of the server or the network it's on. In part, this is provided by the `/etc/ppp/options` file, where the administrator can place options to require authentication whenever `pppd` is run, and in part by the PAP and CHAP secrets files, where the administrator can restrict the set of IP addresses that individual users can use.

The default behavior of `pppd` is to agree to authenticate if requested and to not require authentication from the peer. However, `pppd` does not agree to authenticate itself with a particular protocol if it has no secrets that can be used to do so.

Authentication is based on secrets, which are selected from secrets files (`/etc/ppp/pap-secrets` for PAP, `/etc/ppp/chap-secrets` for CHAP). Both secrets files have the same format, and both can store secrets for several combinations of server (authenticating peer) and client (peer being authenticated). Note that `pppd` can be both a server and client and that different protocols can be used in the two directions if desired.

A secrets file is parsed into words as for an options file. A secret is specified by a line containing at least three words, in the order client name, server name, and secret. Any following words on the same line are taken to be a list of acceptable IP addresses for that client. If there are only three words on the line, it is assumed that any IP address is okay; to disallow all IP addresses, use `.`. If the secret starts with an `@`, what follows is assumed to be the name of a file from which to read the secret. A `*` as the client or server name matches any name. When selecting a secret, `pppd` takes the best match—that is, the match with the fewest wildcards.

A secrets file contains both secrets for use in authenticating other hosts and secrets that you use for authenticating yourself to others. Which secret to use is chosen based on the names of the host (the local name) and its peer (the remote name). The local name is set as follows:

If the <code>usehostname</code> option is given,	The local name is the hostname of this machine (with the domain appended, if given).
If the <code>name</code> option is given	Use the argument of the first <code>name</code> option seen.
If the local IP address is specified with a hostname	Use that name. Otherwise, use the hostname of this machine (with the domain appended, if given).

When authenticating yourself using PAP, there is also a username, which is the local name by default, but can be set with the `user` option or the `+ua` option.

The remote name is set as follows:

If the <code>remotename</code> option is given	Use the argument of the last <code>remote-name</code> option seen.
If the remote IP address is specified with a hostname	Use that host name. Otherwise, the remote name is the null string <code>"</code> .

Secrets are selected from the PAP secrets file as follows:

- For authenticating the peer, look for a secret with `client == username` specified in the PAP `authenticate-request` and `server == local name`.
- For authenticating yourself to the peer, look for a secret with `client == your username` and `server == remote name`.

When authenticating the peer with PAP, a secret of "" matches any password supplied by the peer. If the password doesn't match the secret, the password is encrypted using `crypt()` and checked against the secret again; thus secrets for authenticating the peer can be stored in encrypted form. If the `papcrypt` option is given, the first (unencrypted) comparison is omitted for better security.

If the `login` option was specified, the username and password are also checked against the system password database. Thus, the system administrator can set up the `pap-secrets` file to allow PPP access only to certain users and to restrict the set of IP addresses that each user can use. Typically, when using the `login` option, the secret in `/etc/ppp/pap-secrets` is "" to avoid the need to have the same secret in two places.

Secrets are selected from the CHAP secrets file as follows:

- For authenticating the peer, look for a secret with `client == name` specified in the CHAP-Response message and `server == local name`.
- For authenticating yourself to the peer, look for a secret with `client == local name` and `server == name` specified in the CHAP-Challenge message.

Authentication must be satisfactorily completed before IPCP (or any other Network Control Protocol) can be started. If authentication fails, `pppd` terminates the link (by closing LCP). If IPCP negotiates an unacceptable IP address for the remote host, IPCP is closed. IP packets can only be sent or received when IPCP is open.

In some cases, it is desirable to allow some hosts that can't authenticate themselves to connect and use one of a restricted set of IP addresses, even when the local host generally requires authentication. If the peer refuses to authenticate itself when requested, `pppd` takes that as equivalent to authenticating with PAP using the empty string for the username and password. Thus, by adding a line to the `pap-secrets` file, which specifies the empty string for the client and password, it is possible to allow restricted access to hosts that refuse to authenticate themselves.

ROUTING

When IPCP negotiation is completed successfully, `pppd` informs the kernel of the local and remote IP addresses for the PPP interface. This is sufficient to create a host route to the remote end of the link, which enables the peers to exchange IP packets. Communication with other machines generally requires further modification to routing tables and/or ARP (Address Resolution Protocol) tables. In some cases, this is done automatically through the actions of the routed or gated daemons, but in most cases, some further intervention is required.

Sometimes it is desirable to add a default route through the remote host, as in the case of a machine whose only connection to the Internet is through the PPP interface. The `defaultroute` option causes `pppd` to create such a default route when IPCP comes up and delete it when the link is terminated.

In some cases, it is desirable to use proxy ARP—for example, on a server machine connected to a LAN—to allow other hosts to communicate with the remote host. The `proxyarp` option causes `pppd` to look for a network interface on the same subnet as the remote host (an interface supporting broadcast and ARP, which is up and not a point-to-point or loopback interface). If found, `pppd` creates a permanent, published ARP entry with the IP address of the remote host and the hardware address of the network interface found.

EXAMPLES

In the simplest case, you can connect the serial ports of two machines and issue a command like

```
pppd /dev/ttya 9600 passive
```

to each machine, assuming there is no `getty` running on the serial ports. If one machine has a `getty` running, you can use `kermit` or `tip` on the other machine to log in to the first machine and issue a command like

```
pppd passive
```

Then exit from the communications program (making sure the connection isn't dropped) and issue a command like

```
pppd /dev/ttya 9600
```

The process of logging in to the other machine and starting `pppd` can be automated by using the `connect` option to run `chat`:

```
pppd /dev/ttya 38400 connect 'chat "" "" "login:" "username"
"Password:" "pass-word" "% " "exec pppd passive"
```

(Note, however, that running `chat` like this leaves the password visible in the parameter list of `pppd` and `chat`.)

If your serial connection is any more complicated than a piece of wire, you might need to arrange for some control characters to be escaped. In particular, it is often useful to escape XON (^Q) and XOFF (^S), using `asynmap a0000`. If the path includes a telnet, you probably should escape `^]` as well (`asynmap 200a0000`). If the path includes an `rlogin`, you need to use the `escape ff` option on the end that is running the `rlogin` client because many `rlogin` implementations are not transparent; they remove the sequence (0xff, 0xff, 0x73, 0x73, followed by any 8 bytes) from the stream.

DIAGNOSTICS

Messages are sent to the `syslog` daemon using the facility `LOG_DAEMON`. (This can be overridden by recompiling `pppd` with the macro `LOG_PPP` defined as the desired facility.) To see the error and debug messages, you need to edit your `/etc/syslog.conf` file to direct the messages to the desired output device or file.

The `debug` option causes the contents of all control packets sent or received to be logged—that is, all LCP, PAP, CHAP, or IPCP packets. This can be useful if the PPP negotiation does not succeed. If debugging is enabled at compile time, the `debug` option also causes other debugging messages to be logged.

Debugging can also be enabled or disabled by sending a `SIGUSR1` to the `pppd` process. This signal acts as a toggle.

FILES

`/var/run/pppn.pid` (BSD or Linux)

Process-ID for `pppd` process on PPP interface unit `n`.

`/etc/ppp/pppn.pid` (others)

`/etc/ppp/ip-up`

A program or script that is executed when the link is available for sending and receiving IP packets (that is, IPCP has come up). It is executed with the parameters `interface-name tty-device speed local-IP-address remote-IP-address` and with its standard input, output and error streams redirected to `/dev/null`.

This program or script is executed with the same real and effective user-ID as `pppd`—that is, at least the effective user-ID and possibly the real user-ID will be root. This is so that it can be used to manipulate routes, run privileged daemons (such as `send-mail`), and so on. Be careful that the contents of the `/etc/ppp/ip-up` and `/etc/ppp/ip-down` scripts do not compromise your system's security.

`/etc/ppp/ip-down`

A program or script that is executed when the link is no longer available for sending and receiving IP packets. This script can be used for undoing the effects of the `/etc/ppp/ip-up` script. It is invoked with the same parameters as the `ip-up` script, and the same security considerations apply because it is executed with the same effective and real user-IDs as `pppd`.

`/etc/ppp/ipx-up`

A program or script that is executed when the link is available for sending and receiving IPX packets (that is, IPXCP has come up). It is executed with the parameters `interface-name tty-device speed network-number local-IPX-node-address remote-IPX-node-address local-IPX-routing-protocol remote-IPX-routing-protocol local-IPX-router-name remote-IPX-router-name ipparam pppd-pid` and with its standard input, output, and error streams redirected to `/dev/null`.

The `local-IPX-routing-protocol` and `remote-IPX-routing-protocol` field may be one of the following:

	NONE to indicate that there is no routing protocol. RIP to indicate that RIP/SAP should be used. NLSP to indicate that Novell NLSP should be used. RIP NLSP to indicate that both RIP/SAP and NLSP should be used.
	This program or script is executed with the same real and effective user-ID as <code>pppd</code> —that is, at least the effective user-ID and possibly the real user-ID will be root. This is so that it can be used to manipulate routes, run privileged daemons (such as <code>ripd</code>), and so on. Be careful that the contents of the <code>/etc/ppp/ix-up</code> and <code>/etc/ppp/ix-down</code> scripts do not compromise your system's security.
<code>/etc/ppp/ix-down</code>	A program or script that is executed when the link is no longer available for sending and receiving IPX packets. This script can be used for undoing the effects of the <code>/etc/ppp/ix-up</code> script. It is invoked with the same parameters as the <code>ix-up</code> script, and the same security considerations apply because it is executed with the same effective and real user-IDs as <code>pppd</code> .
<code>/etc/ppp/pap-secrets</code>	Username, password, and IP addresses for PAP authentication.
<code>/etc/ppp/chap-secrets</code>	Names, secrets, and IP addresses for CHAP authentication.
<code>/etc/ppp/options</code>	System default options for <code>pppd</code> , read before user default options or command-line options.
<code>~/.ppprc</code>	User default options, read before command-line options.
<code>/etc/ppp/options.ttyname</code>	System default options for the serial port being used, read after command-line options.

NOTES

The following signals have the specified effect when sent to the `pppd` process:

SIGINT, SIGTERM	These signals cause <code>pppd</code> to terminate the link (by closing LCP), restore the serial device settings, and exit.
SIGHUP	This signal causes <code>pppd</code> to terminate the link, restore the serial device settings, and close the serial device. If the <code>persist</code> option has been specified, <code>pppd</code> tries to reopen the serial device and start another connection. Otherwise, <code>pppd</code> exits.
SIGUSR2	This signal causes <code>pppd</code> to renegotiate compression. This can be useful to re-enable compression after it has been disabled as a result of a fatal decompression error. With the BSD Compress scheme, fatal decompression errors generally indicate a bug in one or another implementation.

pppstats

`pppstats`—Print PPP statistics.

SYNOPSIS

```
pppstats [ -v ][-r ][-c ][-i secs][uni t# ]
```

DESCRIPTION

`pppstats` prints PPP-related statistics.

The `-v` flag causes `pppstats` to display additional statistics, such as the number of packets tossed (that is, which the VJ TCP header decompression code rejected).

The `-r` flag causes `pppstats` to display the overall packet compression rate. The rate value is between 0 and 1, with 0 meaning that the data is incompressible.

The `-c` flag is used to specify an alternate display mode that shows packet compression statistics: the number of packets and bytes uncompressed (that is, before compression or after decompression), compressed, and incompressible (packets that did not shrink on compression and were transmitted uncompressed), and the recent compression rate. This rate reflects the recent performance of the compression code rather than the overall rate the code compression was enabled.

The `-i` flag is used to specify the interval between printouts. The default is 5 seconds.

`uni t#` specifies which interface to use for gathering statistics.

prunehistory

`prunehistory`—Remove filenames from Usenet history file.

SYNOPSIS

```
prunehistory [ -f filename ][-p ][input ]
```

DESCRIPTION

`prunehistory` modifies the `history(5)` text file to remove a set of filenames from it. The filenames are removed by overwriting them with spaces so that the size and position of any following entries do not change.

`prunehistory` reads the named input file or standard input if no file is given. The input is taken as a set of lines. Blank lines and lines starting with a number sign (#) are ignored. All other lines should consist of a Message-ID followed by zero or more filenames. `prunehistory` usually complains about lines that do not follow this format. If the `-p` flag is used, then the program silently prints any invalid lines on its standard output. (Blank lines and comment lines are also passed through.) This can be useful when `prunehistory` is used as a filter for other programs such as `reap`.

The Message-ID is used as the `dbz(3)` key to get an offset into the text file. If no filenames are mentioned on the input line, then all filenames in the text are removed. If any filenames are mentioned, they are converted into the history file notation. If they appear in the line for the specified Message-ID, they are removed.

The default name of the history file is `/news/lib/history`; to specify a different name, use the `-f` flag.

Because `innd(8)` only appends to the text file, `prunehistory` does not need to have any interaction with it.

It is a good idea to delete purged entries and rebuild the `dbz` database every so often by using a script such as the following:

```
ctlinnd throttle "Rebuilding history database"
cd /news/lib
awk 'NF > 2 {
printf "%s\t%s\t%s", $1, $2, $3;
for (i = 4; i <= NF; i++)
printf " %s", $i;
print "\n";
}' <history >history.n
if makehistory -r -f history.n ; then
```

```

mv history.n history
mv history.n.pag history.pag
mv history.n.dir history.dir
else
echo 'Problem rebuilding history; old file not replaced'
fi
ctlinnd go "Rebuilding history database"

```

Note that this keeps no record of expired articles.

quotacheck

quotacheck—Scan a filesystem for disk usages.

SYNOPSIS

```

quotacheck [-g] [-u] [-v] -a
quotacheck [-g] [-u] [-v] filesystems ...

```

DESCRIPTION

quotacheck performs a filesystem scan for usage of files and directories, used by either user or group. The output is the quota file for the corresponding filesystem. By default, the names for these files are

A user scan	quota.user
A group scan	quota.group

The resulting file consists of a `struct dqblk` for each possible ID up to the highest existing UID or GID and contains the values for the disk file and block usage and possibly excess time for these values. (For definitions of `struct dqblk`, see `linux/quota.h`.)

quotacheck should be run each time the system boots and mounts non-valid filesystems. This is most likely to happen after a system crash.

The speed of the scan decreases with the amount of directories increasing. The time needed doubles when disk usage is doubled as well. A 100MB partition used for 94 percent is scanned in one minute; the same partition used for 50 percent is done in 25 seconds.

OPTIONS

-v	This way, the program will give some useful information about what it is doing, plus some fancy stuff.
-d	This means debug. It will result in a lot of information that can be used in debugging the program. The output is very verbose and the scan will not be fast.
-u	This flag tells the program to scan the disk and to count the files and directories used by a certain UID. This is the default action.
-g	This flag forces the program to count the files and directories used by a certain GID.

NOTE

checkquota should only be run as superuser. Non-privileged users are presumably not allowed to read all the directories on the given filesystem.

quotaon, quotaoff

quotaon, quotaoff—Turn filesystem quotas on and off.

SYNOPSIS

```
/usr/etc/quotaon [ -vug ] filesystem...
/usr/etc/quotaon [ -avug ]

/usr/etc/quotaoff [ -vug ] filesystem...
/usr/etc/quotaoff [ -avug ]
```

DESCRIPTION

quotaon announces to the system that disk quotas should be enabled on one or more filesystems. The filesystem quota files must be present in the root directory of the specified filesystem and be named quota.user for user quota or quota.group for group quota.

quotaoff announces to the system that filesystems specified should have any disk quotas turned off.

OPTIONS

quotaon

-a All filesystems in /etc/fstab marked read-write with quotas will have their quotas turned on. This is usually used at boot time to enable quotas.
 -v Display a message for each filesystem where quotas are turned on.
 -u Manipulate user quotas. This is the default.
 -g Manipulate group quotas.

quotaoff

-a Force all filesystems in /etc/fstab to have their quotas disabled.
 -v Display a message for each filesystem affected.
 -u Manipulate user quotas. This is the default.
 -g Manipulate group quotas.

FILES

quota.user User quota file at the filesystem root
 quota.group Group quota file at the filesystem root
 /etc/fstab Default filesystems

SEE ALSO

quotact1(2), fstab(5)

rarp

rarp—Manipulate the system RARP table.

SYNOPSIS

```
rarp [-v] [-t type] -a [hostname]
rarp [-v] -d hostname ...
rarp [-v] [-t type] -s hostname hw_addr
```

DESCRIPTION

rarp manipulates the kernel's RARP table in various ways. The primary options are clearing an address mapping entry and manually setting up one. For debugging purposes, the rarp program also allows a complete dump of the RARP table.

OPTIONS

-v	Tell the user what is going on by being verbose.
-t type	When setting or reading the RARP table, this optional parameter tells rarp which class of entries it should check for. The default value of this parameter is ether (hardware code 0x01 for IEEE 802.3 10Mbps Ethernet). Other values might include network technologies such as AX.25 (ax25).
-a [hostname]	Shows the entries of the specified hosts. If the hostname parameter is not used, all entries are displayed.
-d hostname	Remove the entries of the specified host. This can be used if the indicated host is brought down, for example.
-s hostname hw_addr	Create an RARP address mapping entry for host hostname with hardware address set to hw_addr class, but for most classes, you can assume that the usual presentation can be used. For the Ethernet class, this is 6 bytes in hexadecimal, separated by colons.

FILES

/proc/net/rarp

rdev

rdev—Query/set image root device, swap device, RAM disk size, or video mode.

SYNOPSIS

```
rdev [ -rsvh ] [ -o offset ][image [ value [ offset ]]]
rdev [ -o offset ][image [ root_device [ offset ]]]
swapdev [ -o offset ][image [ swap_device [ offset ]]]
ramsize [ -o offset ][image [ size [ offset ]]]
vidmode [ -o offset ][image [ mode [ offset ]]]
rootflags [ -o offset ][image [ flags [ offset ]]]
```

DESCRIPTION

With no arguments, `rdev` outputs an `/etc/mtab` line for the current root filesystem. With no arguments, `swapdev`, `ramsize`, `vidmode`, and `rootflags` print usage information.

In a bootable image for the Linux kernel, there are several pairs of bytes that specify the root device, the video mode, the size of the RAM disk, and the swap device. These pairs of bytes, by default, begin at offset 504 (decimal) in the kernel image:

- 498 Root flags
- (500 and 502 Reserved)
- 504 RAM Disk Size
- 506 VGA Mode
- 508 Root Device
- (510 Boot Signature)

`rdev` changes these values.

Typical values for the image parameter, which is a bootable Linux kernel image, are as follows:

```
/vmlinux
/vmlinux.test
/vmunix
/vmunix.test
/dev/fd0
/dev/fd1
```

When using the `rdev` or `swapdev` commands, the root device or swap device parameter are as follows:

```
/dev/hda[1-8]
/dev/hdb[1-8]
/dev/sda[1-8]
/dev/sdb[1-8]
```

For the `ramsize` command, the `size` parameter specifies the size of the RAM disk in kilobytes.

For the `rootflags` command, the `flags` parameter contains extra information used when mounting root. Currently, the only effect of these flags is to force the kernel to mount the root filesystem in read-only mode if `flags` is nonzero.

For the `vidmode` command, the `mode` parameter specifies the video mode:

-3	Prompt
-2	Extended VGA
-1	Normal VGA
0	As if 0 was pressed at the prompt
1	As if 1 was pressed at the prompt
2	As if 2 was pressed at the prompt
n	As if n was pressed at the prompt

If the value is not specified, the image is examined to determine the current settings.

OPTIONS

-s	Causes <code>rdev</code> to act like <code>swapdev</code> .
-r	Causes <code>rdev</code> to act like <code>ramsize</code> .
-R	Causes <code>rdev</code> to act like <code>rootflags</code> .
-v	Causes <code>rdev</code> to act like <code>vidmode</code> .
-h	Provides help.

BUGS

For historical reasons, there are two methods for specifying alternative values for the offset.

The user interface is cumbersome, non-intuitive, and should probably be rewritten from scratch, allowing multiple kernel image parameters to be changed or examined with a single command.

If LILO is used, `rdev` is no longer needed for setting the root device and the VGA mode because the parameters that `rdev` modifies can be set from the LILO prompt during a boot. However, `rdev` is still needed at this time for setting the RAM disk size. Users are encouraged to find the LILO documentation for more information and to use LILO when booting their systems.

AUTHORS

Originally by Werner Almesberger (almesber@nessie.cs.id.ethz.ch). Modified by Peter MacDonald (pmacdona@sanjuan.UVic.CA). `rootflags` support added by Stephen Tweedie (sct@dcs.ed.ac.uk).

Linux 0.99, 20 November 1993

renice

`renice`—Alter priority of running processes.

SYNOPSIS

```
renice priority [[-p] pid ...] [[-g] pgrp ...] [[-u] user ...]
```

DESCRIPTION

`renice` alters the scheduling priority of one or more running processes. The following “who” parameters are interpreted as process IDs, process group IDs, or user names. `renice`ing a process group causes all processes in the process group to have their scheduling priority altered. `renice`ing a user causes all processes owned by the user to have their scheduling priority altered. By default, the processes to be affected are specified by their process IDs.

Options supported by `renice`:

<code>-g</code>	Force who parameters to be interpreted as process group IDs.
<code>-u</code>	Force the who parameters to be interpreted as usernames.
<code>-p</code>	Reset the who interpretation to be (the default) process IDs.

The following example changes the priority of process IDs 987 and 32 and all processes owned by users `daemon` and `root`:

```
renice +1 987 -u daemon root -p 32
```

Users other than the superuser can only alter the priority of processes they own and can only monotonically increase their “nice value” within the range 0 to `PRIO_MAX` (20). (This prevents overriding administrative fiats.) The superuser can alter the priority of any process and set the priority to any value in the range `PRIO_MIN` (-20) to `PRIO_MAX`. Useful priorities are: 20 (the affected processes run only when nothing else in the system wants to), 0 (the “base” scheduling priority), and anything negative (to make things go very fast).

FILES

`/etc/passwd` to map usernames to user IDs

SEE ALSO

`getpriority(2)`, `setpriority(2)`

BUGS

Non-superusers cannot increase scheduling priorities of their own processes, even if they were the ones that decreased the priorities in the first place.

HISTORY

The `renice` command appeared in BSD 4.0.

BSD 4, 9 June 1993

repquota

`repquota`—Summarize quotas for a filesystem.

SYNOPSIS

```
/usr/etc/repquota [ -vug ] filesystem...
/usr/etc/repquota [ -avug ]
```

DESCRIPTION

`repquota` prints a summary of the disk usage and quotas for the specified filesystems. For each user, the current number of files and amount of space (in kilobytes) is printed, along with any quotas created with `edquota(8)`.

OPTIONS

-a	Report on all filesystems indicated in <code>/etc/fstab</code> to be read-write with quotas.
-v	Report all quotas even if there is no usage.
-g	Report quotas for groups.
-u	Report quotas for users. This is the default.

Only the superuser can view quotas that are not their own.

FILES

<code>quotas</code>	Quota file at the filesystem root
<code>/etc/fstab</code>	Default filesystems

SEE ALSO

`quota(1)`, `quotactl(2)`, `edquota(8)`, `quotacheck(8)`, `quotaon(8)`

rexecd

`rexecd`—Remote execution server.

SYNOPSIS

```
rexecd
```

DESCRIPTION

`rexecd` is the server for the `rexec(3)` routine. The server provides remote execution facilities with authentication based on usernames and passwords.

`rexecd` listens for service requests at the port indicated in the `exec` service specification; see `services(5)`. When a service request is received, the following protocol is initiated:

1. The server reads characters from the socket up to a null `\0` byte. The resultant string is interpreted as an ASCII number, base 10.

2. If the number received in Step 1 is nonzero, it is interpreted as the port number of a secondary stream to be used for the `stderr`. A second connection is then created to the specified port on the client's machine.
3. A null-terminated username of at most 16 characters is retrieved on the initial socket.
4. A null-terminated, unencrypted password of at most 16 characters is retrieved on the initial socket.
5. A null-terminated command to be passed to a shell is retrieved on the initial socket. The length of the command is limited by the upper bound on the size of the system's argument list.
6. `rexecd` then validates the user as is done at login time and, if the authentication was successful, changes to the user's home directory and establishes the user and group protections of the user. If any of these steps fail, the connection is aborted with a diagnostic message returned.
7. A null byte is returned on the initial socket and the command line is passed to the normal login shell of the user. The shell inherits the network connections established by `rexecd`.

DIAGNOSTICS

Except for the last one listed, all diagnostic messages are returned on the initial socket, after which any network connections are closed. An error is indicated by a leading byte with a value of 1 (0 is returned in Step 7 upon successful completion of all the steps prior to the command execution).

username too long	The name is longer than 16 characters.
password too long	The password is longer than 16 characters.
command too long	The command line passed exceeds the size of the argument list (as configured into the system).
Login incorrect.	No password file entry for the username existed or the wrong password was supplied.
No remote directory.	The <code>chdir</code> command to the home directory failed.
Try again.	A fork by the server failed.
<shell name>: ...	The user's login shell could not be started. This message is returned on the connection associated with the <code>stderr</code> and is not preceded by a flag byte.

SEE ALSO

`rexec(3)`

BUGS

A facility to allow all data and password exchanges to be encrypted should be present.

HISTORY

The `rexecd` command appeared in BSD 4.2.

BSD 4.2, 16 March 1991

rlogind

`rlogind`—Remote login server.

SYNOPSIS

`rlogind [-aln]`

DESCRIPTION

`rlogind` is the server for the `rlogin(1)` program. The server provides a remote login facility with authentication based on privileged port numbers from trusted hosts.

Options supported by `rlogind`:

- a Ask hostname for verification.
- l Prevent any authentication based on the user's `.rhosts` file unless the user is logging in as the superuser.
- n Disable keep-alive messages.

`rlogind` listens for service requests at the port indicated in the “login” service specification; see `services(5)`. When a service request is received, the following protocol is initiated:

1. The server checks the client's source port. If the port is not in the range 512-1023, the server aborts the connection.
2. The server checks the client's source address and requests the corresponding hostname (see `gethostbyaddr(3)`, `hosts(5)`, and `named(8)`). If the hostname cannot be determined, the dot-notation representation of the host address is used. If the hostname is in the same domain as the server (according to the last two components of the domain name), or if the `-a` option is given, the addresses for the hostname are requested, verifying that the name and address correspond. Normal authentication is bypassed if the address verification fails.

Once the source port and address have been checked, `rlogind` proceeds with the authentication process described in `rshd(8)`. It then allocates a pseudo terminal (see `pty(4)`) and manipulates file descriptors so that the slave half of the pseudo terminal becomes the `stdin`, `stdout`, and `stderr` for a login process. The login process is an instance of the `login(1)` program, invoked with the `-f` option if authentication has succeeded. If automatic authentication fails, the user is prompted to log in as if on a standard terminal line.

The parent of the login process manipulates the master side of the pseudo terminal, operating as an intermediary between the login process and the client instance of the `rlogin` program. In normal operation, the packet protocol described in `pty(4)` is invoked to provide `S/Q` type facilities and propagate interrupt signals to the remote programs. The login process propagates the client terminal's baud rate and terminal type, as found in the environment variable, `TERM`; see `environ(7)`. The screen or window size of the terminal is requested from the client, and window size changes from the client are propagated to the pseudo terminal.

Transport-level keep-alive messages are enabled unless the `-n` option is present. The use of keep-alive messages allows sessions to be timed out if the client crashes or becomes unreachable.

DIAGNOSTICS

All initial diagnostic messages are indicated by a leading byte with a value of 1, after which any network connections are closed. If there are no errors before login is invoked, a null byte is returned as an indication of success.

Try again. A fork by the server failed.

SEE ALSO

`login(1)`, `ruserok(3)`, `rshd(8)`

BUGS

The authentication procedure used here assumes the integrity of each client machine and the connecting medium. This is insecure but is useful in an “open” environment.

A facility to allow all data exchanges to be encrypted should be present.

A more extensible protocol should be used.

HISTORY

The `rlogind` command appeared in BSD 4.2.

route

route—Show/manipulate the IP routing table.

SYNOPSIS

```
route [ -vn ]
route [ -v ] add [ -net | -host ] XXXX [gw GGGG] [metric MMMM] [netmask NNNN]
[mss NNNN] [window NNNN] [dev DDDD]
route [ -v ] del XXXX
```

DESCRIPTION

route manipulates the kernel's IP routing table. Its primary use is to set up static routes to specific hosts or networks via an interface after it has been configured with the `ifconfig(8)` program. This version of `route` is intended solely for use with kernel versions 0.99p14n and newer kernels.

OPTIONS

(none)	Prints out the kernel routing table, listing destination address, gateway, netmask for route ("Genmask"), flags (U = Up, H = Host, G = Gateway, D = dynamic, M = Modified), Metric (currently not supported), Ref, Use, and Iface (which device the route maps to).
-n	Same as previous but shows numerical addresses instead of trying to determine symbolic host names.
-v	A flag for verbose (not actually used).
del XXXX	Deletes the route associated with the destination address XXXX.
add[-net -host] XXXX [gw GGGG] [metric MMMM] [netmask NNNN] [dev DDDD]	<p>Adds a route to the IP address XXXX. The route is a network route if the <code>-net</code> modifier is used or XXXX is found in <code>/etc/networks</code> by the <code>getnetbyname()</code> library function and no <code>-host</code> modifier is used.</p> <p>The <code>gw GGGG</code> argument means that any IP packets sent to this address will be routed through the specified gateway. Note: The specified gateway must be reachable first. This usually means that you have to set up a static route to the gateway beforehand.</p> <p>The <code>metric MMMM</code> modifier is not yet implemented (and with the <code>-v</code> option will actually print a warning).</p> <p>The <code>netmask NNNN</code> modifier specifies the netmask of the route to be added. This only makes sense for a network route and when the address XXXX actually makes sense with the specified netmask. If no netmask is given, <code>route</code> guesses it instead, so for most normal setups, you won't need to specify a netmask.</p> <p>The <code>mss NNNN</code> modifier specifies the TCP <code>mss</code> for the route to be added. This is usually used only for fine optimization of routing setups.</p> <p>The <code>window NNNN</code> modifier specifies the TCP window for the route to be added. This is typically only used on AX.25 networks and with drivers unable to handle back-to-back frames—such as the 3c501 or DE600.</p> <p>The <code>dev DDDD</code> modifier forces the route to be associated with the specified device because the kernel will otherwise try to determine the device on its own (by checking already existing routes and device specifications and where the route is added to). In most normal networks, you won't need this.</p> <p>If <code>dev DDDD</code> is the last option on the command line, the word <code>dev</code> may be omitted because it's the default. Otherwise, the order of the route modifiers (<code>metric</code>, <code>netmask</code>, <code>gw</code>, and <code>dev</code>) doesn't matter.</p>

EXAMPLES

```
route add -net 127.0.0.0
```

Adds the normal loopback entry, using netmask 255.0.0.0 (Class A net determined from the destination address) and associated with the `lo` device (assuming this device was previously set up correctly with `ifconfig(8)`).

```
route add -net 192.56.76.0
netmask 255.255.255.0 dev eth0
```

Adds a route to the network 192.56.76.x via `eth0`. The Class C netmask modifier is not really necessary here because 192.* is a Class C IP address. The word `dev` can be omitted here.

```
route add default gw mango-gw
```

Adds a default route (which will be used if no other route matches). All packets using this route will be gatewayed through `mango-gw`. The device that will actually be used for that route depends on how you can reach `mango-gw`; the static route to `mango-gw` will have to be set up before.

```
route add ipx4 sl0 route add -net
192.57.66.0 netmask 255.255.255.0
gw ipx4
```

This command sequence adds the route to the `ipx4` host via the SLIP interface (assuming that `ipx4` is the SLIP host) and then adds the net 192.57.66.0 to be gatewayed through that host.

FILES

```
/proc/net/route
/etc/networks
/etc/hosts
```

SEE ALSO

`ifconfig(8)`

HISTORY

`route` for Linux was originally written by Fred N. van Kempen (waltje@uwal.t.n1.mugnet.org) and then modified by Johannes Stille and Linus Torvalds for `pl15`. Alan Cox added the `mss` and `window` options for Linux 1.1.22.

14 June 1994

route

`route`—Network routing daemon.

SYNOPSIS

```
route [-d] [-g] [-q] [-s] [-t] [logfile]
```

DESCRIPTION

`route` is invoked at boot time to manage the network routing tables. The routing daemon uses a variant of the Xerox NS Routing Information Protocol in maintaining up-to-date kernel routing table entries. It used a generalized protocol capable of use with multiple address types but is currently used only for Internet routing within a cluster of networks.

In normal operation, `route` listens on the `udp(4)` socket for the `route(8)` service (see `services(5)`) for routing information packets. If the host is an internetwork router, it periodically supplies copies of its routing tables to any directly connected hosts and networks.

When `route` is started, it uses the `SIOCGIFCONF` `ioctl(2)` to find those directly connected interfaces configured into the system and marked “up” (the software loopback interface is ignored). If multiple interfaces are present, it is assumed that the host will forward packets between networks. `route` then transmits a request packet on each interface (using a broadcast packet if the interface supports it) and enters a loop, listening for request and response packets from other hosts.

When a request packet is received, `routed` formulates a reply based on the information maintained in its internal tables. The response packet generated contains a list of known routes, each marked with a "hop count" metric (a count of 16, or greater, is considered "infinite"). The metric associated with each route returned provides a metric relative to the sender.

Response packets received by `routed` are used to update the routing tables if one of the following conditions is satisfied:

- No routing table entry exists for the destination network or host, and the metric indicates the destination is "reachable" (the hop count is not infinite).

- The source host of the packet is the same as the router in the existing routing table entry. That is, updated information is being received from the very internetwork router through which packets for the destination are being routed.

- The existing entry in the routing table has not been updated for some time (defined to be 90 seconds) and the route is at least as cost effective as the current route.

- The new route describes a shorter route to the destination than the one currently stored in the routing tables; the metric of the new route is compared against the one stored in the table to decide this.

When an update is applied, `routed` records the change in its internal tables and updates the kernel routing table. The change is reflected in the next response packet sent.

In addition to processing incoming packets, `routed` also periodically checks the routing table entries. If an entry has not been updated for three minutes, the entry's metric is set to infinity and marked for deletion. Deletions are delayed an additional 60 seconds to ensure the invalidation is propagated throughout the local Internet.

Hosts acting as internetwork routers gratuitously supply their routing tables every 30 seconds to all directly connected hosts and networks. The response is sent to the broadcast address on nets capable of that function, to the destination address on point-to-point links, and to the router's own address on other networks. The normal routing tables are bypassed when sending gratuitous responses. The reception of responses on each network is used to determine that the network and interface are functioning correctly. If no response is received on an interface, another route may be chosen to route around the interface, or the route may be dropped if no alternative is available.

Options supported by `routed`:

- d Enable additional debugging information to be logged, such as bad packets received.
- g This flag is used on internetwork routers to offer a route to the "default" destination. This is typically used on a gateway to the Internet or on a gateway that uses another routing protocol whose routes are not reported to other local routers.
- s Supplying this option forces `routed` to supply routing information whether it is acting as an internetwork router or not. This is the default if multiple network interfaces are present or if a point-to-point link is in use.
- q This is the opposite of the -s option.
- t If the -t option is specified, all packets sent or received are printed on the standard output. In addition, `routed` will not divorce itself from the controlling terminal so that interrupts from the keyboard will kill the process.

Any other argument supplied is interpreted as the name of file in which `routed`'s actions should be logged. This log contains information about any changes to the routing tables and, if not tracing all packets, a history of recent messages sent and received that are related to the changed route.

In addition to the facilities described previously, `routed` supports the notion of "distant" passive and active gateways. When `routed` is started, it reads the file to find gateways that might not be located using only information from the `SI0GIFCONFioct1` (2). Gateways specified in this manner should be marked passive if they are not expected to exchange routing information, whereas gateways marked active should be willing to exchange routing information (that is, they should have a `routed` process running on the machine). Routes through passive gateways are installed in the kernel's routing tables once upon startup. Such routes are not included in any routing information transmitted. Active gateways are treated equally to network interfaces. Routing information is distributed to the gateway, and if no routing information is received for a period of the time, the associated route is deleted. Gateways marked external are also passive but are not placed in the kernel routing table.

nor are they included in routing updates. The function of external entries is to inform `routed` that another routing process will install such a route and that alternate routes to that destination should not be installed. Such entries are only required when both routers might learn of routes to the same destination.

The `/etc/gateways` is comprised of a series of lines, each in the following format:

```
<net|host> name1 gateway name2 metric value <passive|active|external>
```

The `net` or `host` keyword indicates if the route is to a network or specific host.

`name1` is the name of the destination network or host. This can be a symbolic name located in or known to the name server if started after `named(8)` or an Internet address specified in “dot” notation; see `inet(3)`.

`name2` is the name or address of the gateway to which messages should be forwarded.

`value` is a metric indicating the hop count to the destination host or network.

One of the keywords `passive`, `active`, or `external` indicates if the gateway should be treated as passive or active (as described previously) or whether the gateway is external to the scope of the routed protocol.

Internetwork routers that are directly attached to the ARPANet or Milnet should use the Exterior Gateway Protocol (EGP) to gather routing information rather than use a static routing table of passive gateways. EGP is required in order to provide routes for local networks to the rest of the Internet system. Sites needing assistance with such configurations should contact the Computer Systems Research Group at Berkeley.

Internet Transport Protocols, XSI 028112, Xerox System Integration Standard

BUGS

The kernel's routing tables may not correspond to those of `routed` when redirects change or add routes. `routed` should note any redirects received by reading the ICMP packets received via a raw socket.

`routed` should incorporate other routing protocols, such as Xerox NS, `XNSrouted(8)`, and EGP. Using separate processes for each requires configuration options to avoid redundant or competing routes.

`routed` should listen to intelligent interfaces, such as an IMP, to gather more information. It does not always detect unidirectional failures in network interfaces (such as when the output side fails).

HISTORY

The `routed` command appeared in BSD 4.2.

BSD 4.2, 16 March 1991

rpc.rusersd

`rpc.rusersd`—Logged-in users server.

SYNOPSIS

```
/usr/libexec/rpc.rusersd
```

DESCRIPTION

`rpc.rusersd` is a server that returns information about users currently logged in to the system.

The currently logged-in users are queried using the `rusers(1)` command. The `rpc.rusersd` daemon is usually invoked by `inetd(8)`.

`rpc.rusersd` uses an RPC protocol defined in `/usr/include/rpcsvc`.

SEE ALSO

`rusers(1)`, `who(1)`, `w(1)`, `inetd(8)`

BSD 4.3, 7 June 1993

rpc.rwalld

`rpc.rwalld`—Write messages to users currently logged in to the server.

SYNOPSIS

`/usr/libexec/rpc.rwalld`

DESCRIPTION

`rpc.rwalld` is a server that will send a message to users currently logged in to the system. This server invokes the `wall(1)` command to actually write the messages to the system.

Messages are sent to this server by the `rwall(1)` command. The `rpc.rwalld` daemon is usually invoked by `inetd(8)`.

`rpc.rwalld` uses an RPC protocol defined in `/usr/include/rpcsvc/rwall.x`.

SEE ALSO

`rwall(1)`, `wall(1)`, `inetd(8)`

BSD 4.3, 7 June 1993

rpcinfo

`rpcinfo`—Report RPC information.

SYNOPSIS

```
rpcinfo -p [host]
rpcinfo [-n portnum] -u host program [version]
rpcinfo [-n portnum] -t host program [version]
rpcinfo -b program version
rpcinfo -d program version
```

DESCRIPTION

`rpcinfo` makes an RPC call to an RPC server and reports what it finds.

OPTIONS

- p Probe the port mapper on `host` and print a list of all registered RPC programs. If `host` is not specified, it defaults to the value returned by `hostname(1)`.
- u Make an RPC call to procedure 0 of `program` on the specified `host` using UDP and report whether a response was received.
- t Make an RPC call to procedure 0 of `program` on the specified `host` using TCP and report whether a response was received.
- n Use `portnum` as the port number for the `-t` and `-u` options instead of the port number given by the port mapper.

- b Make an RPC broadcast to procedure 0 of the specified program and version using UDP and report all hosts that respond.
- d Delete registration for the RPC service of the specified program and version. This option can be exercised only by the superuser.

The program argument can be either a name or a number. If a version is specified, `rpcinfo` attempts to call that version of the specified program. Otherwise, `rpcinfo` attempts to find all the registered version numbers for the specified program by calling version 0 (which is presumed not to exist; if it does exist, `rpcinfo` attempts to obtain this information by calling an extremely high version number instead) and attempts to call each registered version. Note that the version number is required for `-b` and `-d` options.

EXAMPLES

To show all the RPC services registered on the local machine, use

```
rpcinfo -p
```

To show all of the RPC services registered on the machine named klaxon, use

```
rpcinfo -p klaxon
```

To show all machines on the local net that are running the Yellow Pages service, use

```
rpcinfo -b ypserv 'version' -- uniq
```

'version' is the current Yellow Pages version obtained from the results of the `-p` switch above.

To delete the registration for version 1 of the `walld` service, use

```
rpcinfo -d walld 1
```

SEE ALSO

`rpc(5)`, `portmap(8)`, *RPC Programming Guide*

BUGS

In releases prior to SunOS 3.0, the Network File System (NFS) did not register itself with the port mapper; `rpcinfo` cannot be used to make RPC calls to the NFS server on hosts running such releases.

17 December 1987

rquotad, rpc.rquotad

`rquotad`, `rpc.rquotad`—Remote quota server.

SYNOPSIS

```
/usr/etc/rpc.rquotad
```

DESCRIPTION

`rquotad` is an `rpc(3N)` server that returns quotas for a user of a local filesystem that is mounted by a remote machine over the NFS. The results are used by `quota(1)` to display user quotas for remote filesystems. The `rquotad` daemon is usually started at boot time from the `rc.net` script.

FILES

`quotas` Quota file at the filesystem root

17 December 1987

rshd

rshd—Remote shell server.

SYNOPSIS

```
rshd [-aInL]
```

DESCRIPTION

The `rshd` server is the server for the `rcmd(3)` routine and, consequently, for the `rsh(1)` program. The server provides remote execution facilities with authentication based on privileged port numbers from trusted hosts.

The `rshd` server listens for service requests at the port indicated in the `cmd` service specification; see `services(5)`. When a service request is received, the following protocol is initiated:

1. The server checks the client's source port. If the port is not in the range 512-1023, the server aborts the connection.
2. The server reads characters from the socket up to a null (`\0`) byte. The resultant string is interpreted as an ASCII number, base 10.
3. If the number received in Step 2 is nonzero, it is interpreted as the port number of a secondary stream to be used for the `stderr`. A second connection is then created to the specified port on the client's machine. The source port of this second connection is also in the range 512-1023.
4. The server checks the client's source address and requests the corresponding hostname (see `gethostbyaddr(3)`, `hosts(5)`, and `named(8)`). If the hostname cannot be determined, the dot-notation representation of the host address is used. If the hostname is in the same domain as the server (according to the last two components of the domain name), or if the `-a` option is given, the addresses for the hostname are requested, verifying that the name and address correspond. If address verification fails, the connection is aborted with the message, `Host address mismatch`.
5. A null-terminated username of at most 16 characters is retrieved on the initial socket. This username is interpreted as the user identity on the client's machine.
6. A null-terminated username of at most 16 characters is retrieved on the initial socket. This username is interpreted as a user identity to use on the server's machine.
7. A null-terminated command to be passed to a shell is retrieved on the initial socket. The length of the command is limited by the upper bound on the size of the system's argument list.
8. `rshd` then validates the user using `ruserok(3)`, which uses the file and the file found in the user's home directory. The `-l` option prevents `ruserok(3)` from doing any validation based on the user's `.rhosts` file, unless the user is the superuser.
9. A null byte is returned on the initial socket and the command line is passed to the normal login shell of the user. The shell inherits the network connections established by `rshd`.

Transport-level keep-alive messages are enabled unless the `-n` option is present. The use of keep-alive messages allows sessions to be timed out if the client crashes or becomes unreachable.

The `-L` option causes all successful accesses to be logged to `syslogd(8)` as `auth.info` messages and all failed accesses to be logged as `auth.notice`.

DIAGNOSTICS

Except for the last one listed, all diagnostic messages are returned on the initial socket, after which any network connections are closed. An error is indicated by a leading byte with a value of 1 (`@`) is returned in Step 9 upon successful completion of all the steps prior to the execution of the login shell).

Locuser too long.	The name of the user on the client's machine is longer than 16 characters.
Ruser too long.	The name of the user on the remote machine is longer than 16 characters.
Command too long.	The command line passed exceeds the size of the argument list (as configured into the system).
Login incorrect.	No password file entry for the username existed.
Remote directory.	The <code>chdir</code> command to the home directory failed.

Permission denied.	The authentication procedure described previously failed.
Can't make pipe.	The pipe needed for the <code>stderr</code> wasn't created.
Can't fork; try again.	A fork by the server failed.
<shell name>: ...	The user's login shell could not be started. This message is returned on the connection associated with the <code>stderr</code> and is not preceded by a flag byte.

SEE ALSO

`rsh(1)`, `rcmd(3)`, `ruserok(3)`

BUGS

The authentication procedure used here assumes the integrity of each client machine and the connecting medium. This is insecure but is useful in an “open” environment.

A facility to allow all data exchanges to be encrypted should be present.

A more extensible protocol (such as Telnet) should be used.

BSD 4.2, 30 April 1991

rwhod

`rwhod`—System status server.

SYNOPSIS

`rwhod`

DESCRIPTION

`rwhod` is the server that maintains the database used by the `rwho(1)` and `ruptime(1)` programs. Its operation is predicated on the ability to broadcast messages on a network.

`rwhod` operates as both a producer and consumer of status information. As a producer of information, it periodically queries the state of the system and constructs status messages that are broadcast on a network. As a consumer of information, it listens for other `rwhod` servers' status messages, validating them and then recording them in a collection of files located in the directory.

The server transmits and receives messages at the port indicated in the `rwho` service specification; see `services(5)`. The messages sent and received are of the form:

```
struct outmp {
char out_line[8]; /* tty name */
char out_name[8]; /* user id */
long out_time; /* time on */
};

struct whod {
char wd_vers;
char wd_type;
char wd_fill[2];
int wd_sendtime;
int wd_recvtime;
char wd_hostname[32];
int wd_loadav[3];
int wd_boottime;
struct whoent {
struct outmp we_utmp;
```

```

        int    we_idle;
    } wd_we[1024 / sizeof (struct whoent)];
};

```

All fields are converted to network byte order prior to transmission. The load averages are as calculated by the `w(1)` program and represent load averages over the 5-, 10-, and 15-minute intervals prior to a server's transmission; they are multiplied by 100 for representation in an integer. The hostname included is that returned by the `gethostname(2)` system call, with any trailing domain name omitted. The array at the end of the message contains information about the users logged in to the sending machine. This information includes the contents of the `utmp(5)` entry for each non-idle terminal line and a value indicating the time in seconds since a character was last received on the terminal line.

Messages received by the `rwho` server are discarded unless they originated at an `rwho` server's port. In addition, if the host's name, as specified in the message, contains any unprintable ASCII characters, the message is discarded. Valid messages received by `rwhod` are placed in files named in the directory. These files contain only the most recent message, in the format described previously.

Status messages are generated approximately once every three minutes. `rwhod` performs an `nlist(3)` every 30 minutes to guard against the possibility that this file is not the system image currently operating.

SEE ALSO

`rwho(1)`, `ruptime(1)`

BUGS

There should be a way to relay status information between networks. Status information should be sent only upon request rather than continuously. People often interpret the server dying or network communication failures as a machine going down.

HISTORY

The `rwhod` command appeared in BSD 4.2.

BSD 4.2, 16 March 1991

sendmail

sendmail—Send mail over the Internet.

SYNOPSIS

```

sendmail [flags] [address ...]
newaliases
mailq [-v]
smtpd
bsmtp
runq

```

DESCRIPTION

`sendmail` sends a message to one or more recipients, routing the message over whatever networks are necessary. `sendmail` does internetwork forwarding as necessary to deliver the message to the correct place.

`sendmail` is not intended as a user interface routine. Other programs provide user-friendly front ends. `sendmail` is used only to deliver preformatted messages.

With no flags, `sendmail` reads its standard input up to an end-of-file or a line consisting only of a single dot and sends a copy of the message found there to all the addresses listed. It determines the networks to use based on the syntax and contents of the addresses.

Local addresses are looked up in a file and aliased appropriately. Aliasing can be prevented by preceding the address with a backslash. Usually, the sender is not included in any alias expansions; for example, if `john` sends to `group` and `group` includes `john` in the expansion, then the letter will not be delivered to `john`.

Flags are

- ba Go into ARPANET mode. All input lines must end with a CR-LF, and all messages will be generated with a CR-LF at the end. Also, the From: and Sender: fields are examined for the name of the sender.
- bd Run as a daemon. This requires Berkeley IPC. `sendmail` will fork and run in the background, listening on socket 25 for incoming SMTP connections. This is usually run from `/etc/rc`.
- bi Initialize the alias database.
- bm Deliver mail in the usual way (default).
- bp Print a listing of the queue.
- bs Use the SMTP protocol as described in RFC 821 on standard input and output. This flag implies all the operations of the `-ba` flag that are compatible with SMTP.
- bb Read batched SMTP (BSMTP) commands from standard input.
- bt Run in address test mode. This mode reads addresses and shows the steps in parsing; it is used for debugging configuration tables.
- bv Verify names only; do not try to collect or deliver a message. Verify mode is usually used for validating users or mailing lists.
- bz Create the configuration freeze file.
- C file Use alternate configuration file. `sendmail` refuses to run as root if an alternate configuration file is specified. The frozen configuration file is bypassed.
- d X Set debugging value to X.
- F full name Set the full name of the sender.
- f name Sets the name of the “from” person (the sender of the mail). `-f` can only be used by trusted users (usually root, daemon, and network) or if the person you are trying to become is the same as the person you are.
- h N Set the hop count to N. The hop count is incremented every time the mail is processed. When it reaches a limit, the mail is returned with an error message, the victim of an aliasing loop. If not specified, Received: lines in the message are counted.
- n Don't do aliasing.
- o x value Set option x to the specified value. Options are described later in this section.
- q time Processed saved messages in the queue at given intervals. If time is omitted, process the queue once. time is given as a tagged number, with s being seconds, m being minutes, h being hours, d being days, and w being weeks. For example, `-q1h30m` or `-q90m` both set the time-out to 1 hour, 30 minutes. If time is specified, `sendmail` runs in background. This option can be used safely with `-bd`.
- M ident Process the queued message with the queue ID ident.
- R addr Process the queued messages that have the string addr in one of the recipient addresses.
- S addr Process the queued messages that have the string addr in the sender address.
- r name An alternate and obsolete form of the `-f` flag.
- t Read message for recipients. To:, Cc:, and Bcc: lines are scanned for recipient addresses. The Bcc: line is deleted before transmission. Any addresses in the argument list are suppressed; that is, they do not receive copies even if listed in the message header.
- v Go into verbose mode. Alias expansions are announced and so on.

There are also a number of processing options that can be set. Usually, these will only be used by a system administrator. Options can be set either on the command line using the `-o` flag or in the configuration file. These are described in detail in the *Sendmail Installation and Operation Guide*. The options are

A file	Use alternate alias file.
c	On mailers that are considered “expensive” to connect to, don’t initiate immediate connection. This requires queuing.
d x	Set the delivery mode to x. Delivery modes are i for interactive (synchronous) delivery, b for background (asynchronous) delivery, and q for queue only (actual delivery is done the next time the queue is run).
D	Try to automatically rebuild the alias database if necessary.
e x	Set error processing to mode x. Valid modes are m to mail back the error message, w to “write” back the error message (or mail it back if the sender is not logged in), p to print the errors on the terminal (default), q to throw away error messages (only exit status is returned), and e to do special processing for the BerkNet. If the text of the message is not mailed back by modes m or w and if the sender is local to this machine, a copy of the message is appended to the file in the sender’s home directory.
F mode	The mode to use when creating temporary files.
f	Save UNIX-style From: lines at the front of messages.
g N	The default group ID to use when calling mailers.
H file	The SMTP help file.
i	Do not take dots on a line by themselves as a message terminator.
k N	Checkpoint the queue file after every N successful deliveries (default is 10). This avoids excessive duplicate deliveries when sending to long mailing lists interrupted by system crashes.
L n	The log level.
m	Send also to “me” (the sender) if I am in an alias expansion.
o	If set, this message may have old style headers. If not set, this message is guaranteed to have new style headers (commas instead of spaces between addresses). If set, an adaptive algorithm is used that will correctly determine the header format in most cases.
Q queuedir	Select the directory in which to queue messages.
r timeout	The time-out on reads; if none is set, sendmail will wait forever for a mailer. This option violates the word (if not the intent) of the SMTP specification, so the timeout should probably be fairly large.
S file	Save statistics in the named file.
s	Always instantiate the queue file, even under circumstances where it is not strictly necessary. This provides safety against system crashes during delivery.
T time	Set the time-out on undelivered messages in the queue to the specified time. After delivery has failed (for example, because of a host being down) for this amount of time, failed messages will be returned to the sender. The default is three days.
t stz, dtz	Set the name of the time zone.
U userdatabase	If set, a user database is consulted to get forwarding information. You can consider this an adjunct to the aliasing mechanism, except that the database is intended to be distributed; aliases are local to a particular host. This might not be available if your sendmail does not have the USERDB option compiled in.
u N	Set the default user ID for mailers.
w	If not set, name server lookups will use a query type of ANY to find types CNAME, A, and MX and will cause all existing records to be cached by the local server. If there is (or might be) a wildcard MX in the local domain or its parents that are searched, you must set this

option, which uses a query type of `CNAME` only; otherwise, it causes all fully qualified names to match as names in the local domain.

In aliases, the first character of a name can be a vertical bar to cause interpretation of the rest of the name as a command to pipe the mail to. It might be necessary to quote the name to keep `sendmail` from suppressing the blanks between arguments. For example, a common alias is

```
msgs: "|usr/bin/msgs -s"
```

Aliases can also have the syntax to ask `sendmail` to read the named file for a list of recipients. For example, an alias such as

```
poets: ":include:/usr/local/lib/poets.list"
```

would read for the list of addresses making up the group.

`sendmail` returns an exit status describing what it did. The codes are defined in `syssexits.h`:

<code>EX_OK</code>	Successful completion on all addresses.
<code>EX_NOUSER</code>	Username not recognized.
<code>EX_UNAVAILABLE</code>	Catchall meaning necessary resources were not available.
<code>EX_SYNTAX</code>	Syntax error in address.
<code>EX_SOFTWARE</code>	Internal software error, including bad arguments.
<code>EX_OSERR</code>	Temporary operating system error, such as cannot fork.
<code>EX_NOHOST</code>	Hostname not recognized.
<code>EX_TEMPFAIL</code>	Message could not be sent immediately but was queued.

If invoked as `newaliases`, `sendmail` rebuilds the alias database. If invoked as `mailq`, `sendmail` prints the contents of the mail queue. If invoked as `smtpd`, `sendmail` forks and runs as a daemon. If invoked as `bsmtp`, `sendmail` processes batched SMTP on standard input. If invoked as `runq`, `sendmail` runs through the mail queue and makes what deliveries are possible.

FILES

Except for the file `/etc/sendmail.cf` itself, the following pathnames are all specified in `/etc/sendmail.cf`. Thus, these values are only approximations.

```
/etc/aliases raw data for alias names
/etc/aliases.pag
/etc/aliases.dir database of alias names
/etc/sendmail.cf configuration file
/etc/sendmail.fc frozen configuration
/etc/sendmail.hf help file
/var/log/sendmail.st collected statistics
/var/spool/queue/* temp files
```

HISTORY

The `sendmail` command appeared in BSD 4.2.

setfdprm

setfdprm—Sets user-provided floppy disk parameters.

SYNOPSIS

```
setfdprm [ -p ] device name
setfdprm [ -p ] device size sectors heads tracks stretch gap rate spec1 fmt_gap
setfdprm [ -c ] device
setfdprm [ -y ] device
setfdprm [ -n ] device
```

DESCRIPTION

setfdprm is a utility that can be used to load disk parameters into the auto-detecting floppy devices, to clear old parameter sets, and to disable or enable diagnostic messages.

Without any options, setfdprm loads the device (usually `/dev/fd0` or `/dev/fd1`) with a new parameter set with the name entry found in `/etc/fdprm` (usually named `360/360` and so on). These parameters stay in effect until the media is changed.

OPTIONS

-p device name	Permanently loads a new parameter set for the specified auto-configuring floppy device for the configuration with name in <code>/etc/fdprm</code> . Alternatively, the parameters can be given directly from the command line.
-c device	Clears the parameter set of the specified auto-configuring floppy device.
-y device	Enables format detection messages for the specified auto-configuring floppy device.
-n device	Disables format detection messages for the specified auto-configuring floppy device.

BUGS

This documentation is grossly incomplete.

FILES

`/etc/fdprm`

Linux 0.99, 20 November 1993

setserial

setserial—Get/set Linux serial port information.

SYNOPSIS

```
setserial [ -abqvVW ] device [ parameter1 [ arg ] ] ...
setserial -g [ -abv ] device1 ...
```

DESCRIPTION

setserial is a program designed to set or report the configuration information associated with a serial port. This information includes what I/O port and IRQ a particular serial port is using, whether the break key should be interpreted as the Secure Attention Key, and so on.

During the normal bootup process, only COM ports 1-4 are initialized, using the default I/O ports and IRQ values, as listed. To initialize any additional serial ports, or to change the COM 1-4 ports to a nonstandard configuration, the setserial program should be used. Typically, it is called from an `rc.serial` script, which is usually run out of `/etc/rc.local`.

The device argument or arguments specify the serial device that should be configured or interrogated. It will usually have the following form: `/dev/cua[0-3]`.

If no parameters are specified, `setserial` prints the port type (such as 8250, 16450, 16550, 16550A), the hardware I/O port, the hardware IRQ line, its “baud base,” and some of its operational flags.

If the `-g` option is given, the arguments to `setserial` are interpreted as a list of devices for which the characteristics of those devices should be printed.

Without the `-g` option, the first argument to `setserial` is interpreted as the device to be modified or characteristics to be printed, and any additional arguments are interpreted as parameters that should be assigned to that serial device.

For the most part, superuser privilege is required to set the configuration parameters of a serial port. A few serial port parameters can be set by normal users, however, and these are noted as exceptions in this manual page.

OPTIONS

`setserial` accepts the following options:

- `-a` When reporting the configuration of a serial device, print all available information.
- `-b` When reporting the configuration of a serial device, print a summary of the device's configuration, which might be suitable for printing during the bootup process during the `/etc/rc` script.
- `-q` Be quiet. `setserial` will print fewer lines of output.
- `-v` Be verbose. `setserial` will print additional status output.
- `-V` Display version and exit.
- `-W` Do wild interrupt initialization and exit.

PARAMETERS

The following parameters can be assigned to a serial port.

All argument values are assumed to be in decimal unless preceded by `0x`.

- `port port_number` The `port` option sets the I/O port as described previously.
- `irq irq_number` The `irq` option sets the hardware IRQ as described previously.
- `uart uart_type` This option is used to set the UART type. The permitted types are none, 8250, 16450, 16550, and 16550A. Because the 8250 and 16450 UARTs do not have FIFOs, and because the original 16550 have bugs that make the FIFOs unusable, the FIFO will only be used on chips identified as 16550A UARTs. Setting the UART type to 8250, 16450, or 16550 will enable the serial port without trying to use the FIFO. Using the UART type none will disable the port. Some internal modems are billed as having a “16550A UART with a 1KB buffer.” This is a lie. They do not really have a 16550A-compatible UART; instead, what they have is a 16450-compatible UART with a 1KB receive buffer to prevent receiver overruns. This is important because they do not have a transmit FIFO. Hence, they are not compatible with a 16550A UART, and the autoconfiguration process will correctly identify them as 16450s. If you attempt to override this using the `uart` parameter, you see dropped characters during file transmissions. These UARTs usually have other problems: The `skip` test parameter also often must be specified.
- `autoconfig` When this parameter is given, `setserial` asks the kernel to attempt to automatically configure the serial port. The I/O port must be correctly set; the kernel will attempt to determine the UART type, and if the `auto_irq` parameter is set, Linux will attempt to automatically determine the IRQ. The `autoconfigure` parameter should be given after the `port`, `auto_irq`, and `skip_test` parameters have been specified.

auto_irq	During autoconfiguration, try to determine the IRQ. This feature is not guaranteed to always produce the correct result; some hardware configurations will fool the Linux kernel. It is generally safer not to use the <code>auto_irq</code> feature but rather to specify the IRQ to be used explicitly, using the <code>irq</code> parameter.
^auto_irq	During autoconfiguration, do not try to determine the IRQ.
skip_test	During autoconfiguration, skip the UART test. Some internal modems do not have National Semiconductor compatible UARTs but have cheap imitations instead. Some of these cheesy imitation UARTs do not fully support the loopback detection mode, which is used by the kernel to make sure there really is a UART at a particular address before attempting to configure it. For certain internal modems, you will need to specify this parameter so Linux can initialize the UART correctly.
^skip_test	During autoconfiguration, do not skip the UART test.
baud_base baud_base	This option sets the base baud rate, which is the clock frequency divided by 16. Usually, this value is 115200, which is also the fastest baud rate, which the UART can support.
spd_hi	Use 57.6KB when the application requests 38.4KB. This parameter can be specified by a non-privileged user.
spd_vhi	Use 115KB when the application requests 38.4KB. This parameter can be specified by a non-privileged user.
spd_cust	Use the custom divisor to set the speed when the application requests 38.4KB. In this case, the baud rate is the <code>baud_base</code> divided by the <code>divisor</code> . This parameter can be specified by a non-privileged user.
spd_normal	Use 38.4KB when the application requests 38.4KB. This parameter can be specified by a non-privileged user.
divisor divisor	This option sets the custom divisor. This divisor will be used when the <code>spd_cust</code> option is selected and the serial port is set to 38.4KB by the application. This parameter can be specified by a non-privileged user.
sak	Set the break key at the Secure Attention Key.
^sak	Disable the Secure Attention Key.
fourport	Configure the port as an AST Fourport card.
^fourport	Disable AST Fourport configuration.
close_delay delay	Specify the amount of time, in hundredths of a second, that DTR should remain low on a serial line after the callout device is closed before the blocked dial-in device raises DTR again. The default value of this option is 50, or a half-second delay.
Session_lockout	Lock out callout port (<code>/dev/cuaXX</code>) accesses across different sessions. That is, once a process has opened a port, do not allow a process with a different session ID to open that port until the first process has closed it.
^session_lockout	Do not lock out callout port accesses across different sessions.
pgrp_lockout	Lock out callout port (<code>/dev/cuaXX</code>) accesses across different process groups. That is, once a process has opened a port, do not allow a process in a different process group to open that port until the first process has closed it.
^pgrp_lockout	Do not lock out callout port accesses across different process groups.
hup_notify	Notify a process blocked on opening a dial-in line when a process has finished using a callout line (either by closing it or by the serial line being hung up) by returning <code>EAGAIN</code> to the open. The application of this parameter is for <code>gettys</code> that are blocked on a serial port's dial-in line. This allows the <code>getty</code> to reset the modem (which may have had its configuration modified by the application using the callout device) before blocking on the open again.
^hup_notify	Do not notify a process blocked on opening a dial-in line when the callout device is hung up.

<code>split_termios</code>	Treat the termios settings used by the callout device and the termios settings used by the dial-in devices as separate.
<code>^split_termios</code>	Use the same termios structure to store both the dial-in and callout ports. This is the default option.
<code>callout_nohup</code>	If this particular serial port is opened as a callout device, do not hang up the <code>tty</code> when carrier detect is dropped.
<code>^callout_nohup</code>	Do not skip hanging up the <code>tty</code> when a serial port is opened as a callout device. Of course, the <code>HUPCL</code> termios flag must be enabled if the hangup is to occur.

CONSIDERATIONS OF CONFIGURING SERIAL PORTS

It is important to note that `setserial` merely tells the Linux kernel where it should expect to find the I/O port and IRQ lines of a particular serial port. It does not configure the hardware, the actual serial board, to use a particular I/O port. To do that, you need to physically program the serial board, usually by setting some jumpers or by switching some DIP switches.

This section provides some pointers in helping you decide how you want to configure your serial ports.

The “standard MS-DOS” port associations are

<code>/dev/ttyS0 (COM1), port 0x3f8</code>	IRQ 4
<code>/dev/ttyS1 (COM2), port 0x2f8</code>	IRQ 3
<code>/dev/ttyS2 (COM3), port 0x3e8</code>	IRQ 4
<code>/dev/ttyS3 (COM4), port 0x2e8</code>	IRQ 3

Due to the limitations in the design of the AT/ISA bus architecture, an IRQ line usually cannot be shared between two or more serial ports. If you attempt to do this, one or both serial ports will become unreliable if you try to use both simultaneously. This limitation can be overcome by special multiport serial port boards, which are designed to share multiple serial ports over a single IRQ line. Multiport serial cards supported by Linux include the AST FourPort, the Accent Async board, the Usenet Serial II board, the Bocaboard BB-1004, BB-1008, and BB-2016 boards, and the HUB-6 serial board.

The selection of an alternative IRQ line is difficult because most of them are already used. The following table lists the “standard MS-DOS” assignments of available IRQ lines:

IRQ 3	COM2
IRQ 4	COM1
IRQ 5	LPT2
IRQ 7	LPT1

Most people find that IRQ 5 is a good choice, assuming that there is only one parallel port active in the computer. Another good choice is IRQ 2 (a.k.a. IRQ 9), although this IRQ is sometimes used by network cards, and very rarely will VGA cards be configured to use IRQ 2 as a vertical retrace interrupt. If your VGA card is configured this way, try to disable it so you can reclaim that IRQ line for some other card. It’s not necessary for Linux and most other operating systems.

The only other available IRQ lines are 3, 4, and 7, and these are probably used by the other serial and parallel ports. (If your serial card has a 16-bit card edge connector and supports higher interrupt numbers, then IRQ 10, 11, 12, and 15 are also available.)

On AT class machines, IRQ 2 is seen as IRQ 9, and Linux will interpret it in this manner.

IRQs other than 2 (9), 3, 4, 5, 7, 10, 11, 12, and 15 should not be used because they are assigned to other hardware and cannot, in general, be changed. Here are the “standard” assignments:

IRQ 0	Timer channel 0
IRQ 1	Keyboard
IRQ 2	Cascade for controller 2
IRQ 3	Serial port 2
IRQ 4	Serial port 1

IRQ 5	Parallel port 2 (Reserved in PS/2)
IRQ 6	Floppy diskette
IRQ 7	Parallel port 1
IRQ 8	Real-time clock
IRQ 9	Redirected to IRQ2
IRQ 10	Reserved
IRQ 11	Reserved
IRQ 12	Reserved (Auxiliary device in PS/2)
IRQ 13	Math coprocessor
IRQ 14	Hard disk controller
IRQ 15	Reserved

CAUTION

Using an invalid port can lock up your machine.

FILES

`/etc/rc.local`

`/etc/rc.serial`

AUTHOR

The original version of `setserial` was written by Rick Sladkey (jrs@world.std.com) and was modified by Michael K. Johnson (johnsonm@stolaf.edu).

This version has since been rewritten from scratch by Theodore Ts'o (tytso@mit.edu) on 1/1/93. Any bugs or problems are solely his responsibility.

setserial 2.10, 27 August 1994

setsid

`setsid`—Run a program in a new session.

SYNOPSIS

```
setsid program [ arg ... ]
```

DESCRIPTION

`setsid` runs a program in a new session.

SEE ALSO

`setsid(2)`

AUTHOR

Rick Sladkey (jrs@world.std.com)

Linux 0.99, 20 November 1993

showmount

`showmount`—Show mount information for an NFS server.

SYNOPSIS

```
/usr/etc/showmount [\-adehv\][\--all\][\--directories\]
[\--exports\][\--help\] [\--version\][\host\]
```

DESCRIPTION

`showmount` queries the mount daemon on a remote host for information about the state of the NFS server on that machine. With no options, `showmount` lists the set of clients who are mounting from that host. The output from `showmount` is designed to appear as though it were processed through `sort -u`.

OPTIONS

<code>-a</code> or <code>--all</code>	List both the client hostname and mounted directory in <code>host:dir</code> format.
<code>-d</code> or <code>--directories</code>	List only the directories mounted by some client.
<code>-e</code> or <code>--exports</code>	Show the NFS server's export list.
<code>-h</code> or <code>--help</code>	Provide a short help summary.
<code>-v</code> or <code>--version</code>	Report the current version number of the program.
<code>--no-headers</code>	Suppress the descriptive headings from the output.

SEE ALSO

`rpc.mountd(8)`, `rpc.nfsd(8)`

BUGS

The completeness and accuracy of the information that `showmount` displays varies according to the NFS server's implementation. Because `showmount` sorts and uniques the output, it is impossible to determine from the output whether a client is mounting the same directory more than once.

shutdown

`shutdown`—Close down the system.

SYNOPSIS

```
shutdown [ -h | -r ] [ -fqs ] [ now | hh:ss | +mins ]
reboot [ -h | -r ] [ -fqs ] [ now | hh:ss | +mins ]
fastboot [ -h | -r ] [ -fqs ] [ now | hh:ss | +mins ]
halt [ -h | -r ] [ -fqs ] [ now | hh:ss | +mins ]
fasthalt [ -h | -r ] [ -fqs ] [ now | hh:ss | +mins ]
```

DESCRIPTION

In general, `shutdown` prepares the system for a power down or reboot. An absolute or delta time can be given, and periodic messages will be sent to all users warning of the shutdown.

`halt` is the same as `shutdown -h -q now`.

`fasthalt` is the same as `shutdown -h -q -f now`.

reboot is the same as `shutdown -r -q now`.

fastboot is the same as `shutdown -r -q -f now`.

The default delta time, if none is specified, is two minutes.

Five minutes before shutdown (or immediately, if shutdown is less than five minutes away), the `/etc/nologin` file is created with a message stating that the system is going down and that logins are no longer permitted. The `login(1)` program will not allow non-superusers to log in during this period. A message will be sent to all users at this time.

When the shutdown time arrives, `shutdown` notifies all users, tells `init(8)` not to spawn more `getty(8)s`, writes the shutdown time into the `/var/log/wtmp` file, kills all other processes on the system, `sync(2)s`, unmounts all the disks, `sync(2)s` again, waits for a second, and then either terminates or reboots the system.

OPTIONS

-h	Halt the system. Do not reboot. This option is used when powering down the system.
-r	Reboot the system.
-f	Fast. When the system is rebooted, the filesystems will not be checked. This is arranged by creating <code>/fastboot</code> , which <code>/etc/rc</code> must detect (and delete).
-q	Quiet. This uses a default broadcast message and does not prompt the user for one.
-s	Reboot in single-user mode. This is arranged by creating <code>/etc/singleboot</code> , which <code>simpleinit(8)</code> detects (and deletes).

FILES

`/etc/rc`
`/fastboot`
`/etc/singleboot`
`/etc/nologin`
`/var/log/wtmp`

SEE ALSO

`umount(8)`, `login(1)`, `reboot(2)`, `simpleinit(8)`, `init(8)`

BUGS

Unlike the BSD `shutdown`, users are notified of shutdown only once or twice, instead of many times, and at shorter and shorter intervals as “apocalypse approaches.”

Linux 0.99, 20 November 1993

simpleinit

simpleinit—Process control initialization.

SYNOPSIS

`init [single]`

DESCRIPTION

`init` is invoked as the last step in the Linux boot sequence. If the `single` option is used, or if the file `/etc/singleboot` exists, then single-user mode will be entered, by starting `/bin/sh`. If the file `/etc/securesingle` exists, then the root password will be required to start single-user mode. If the root password does not exist, or if `/etc/passwd` does not exist, the checking of the password will be skipped.

If the file `/etc/TZ` exists, then the contents of that file will be read and used to set the `TZ` environment variable for each process started by `simpleinit`. This “feature” is only available if it’s configured at compile time. It’s not usually needed.

After single-user mode is terminated, the `/etc/rc` file is executed, and the information in `/etc/inittab` will be used to start processes.

While `init` is running, several signals are trapped with special action taken. Because `init` has PID 1, sending signals to the `init` process is easy with the `kill(1)` command.

If `init` catches a `SIGHUP` (hangup) signal, the `/etc/inittab` will be read again. If `init` catches a `SIGTSTP` (terminal stop) signal, no more processes will be spawned. This is a toggle, which is reset if `init` catches another `SIGTSTP` signal.

If `init` catches a `SIGINT` (interrupt) signal, `init` will sync a few times and try to start `reboot`. Failing this, `init` will execute the system `reboot(2)` call. Under Linux, it is possible to configure the `Ctrl+Alt+Del` sequence to send a signal to `init` instead of rebooting the system.

THE `inittab` FILE

Because of the number of `init` programs that are appearing in the Linux community, the documentation for the `/etc/inittab` file, which is usually found with the `inittab(5)` man page, is presented here:

The format is

```
ttyline:termcap-entry:getty-command
```

An example follows:

```
tty1:console:/sbin/getty 9600 tty1
tty2:console:/sbin/getty 9600 tty2
tty3:console:/sbin/getty 9600 tty3
tty4:console:/sbin/getty 9600 tty4
# tty5:console:/sbin/getty 9600 tty5
# ttyS1:dumb:/sbin/getty 9600 ttyS1
# ttyS2:dumb:/sbin/getty -m -t60 2400 ttyS2
```

Lines beginning with the `#` character are treated as comments. Please see documentation for the `getty(8)` command that you are using because there are several of these in the Linux community at this time.

FILES

```
/etc/inittab
/etc/singleboot
/etc/securesingle
/etc/TZ
/etc/passwd
/etc/rc
```

SEE ALSO

`inittab(5)`, `ctrlaltdel(8)`, `reboot(8)`, `termcap(5)`, `getty(8)`, `agetty(8)`, `shutdown(8)`

BUGS

This program is called `simpleinit` to distinguish it from the System V compatible versions of `init` that are starting to appear in the Linux community. `simpleinit` should be linked to, or made identical with, `init` for correct functionality.

Linux 0.99, 20 November 1993

slattach

`slattach`—Attach a network interface to a serial line.

SYNOPSIS

```
slattach [-v] [-p proto] [-s speed] [tty]
```

DESCRIPTION

`slattach` is a little program that can be used to put a normal terminal (“serial”) line into one of several “network” modes, thus allowing you to use it for point-to-point links to other computers.

OPTIONS

<code>[-v]</code>	Enable debugging output. Useful when determining why a given setup doesn’t work.
<code>[-p proto]</code>	Set a specific kind of protocol to use on the line. The default is set to <code>cslip</code> , compressed SLIP. Other possible values are <code>slip</code> (normal SLIP), <code>ppp</code> (Point-to-Point Protocol), and <code>kiss</code> (AX.25 TNC protocol).
<code>[-s speed]</code>	Set a specific line speed other than the default. If no arguments are given, the current terminal line (usually the login device) is used. Otherwise, an attempt is made to claim the indicated terminal port, lock it, and open it.

FILES

`/dev/cua*`

BUGS

None so far.

sliplogin

`sliplogin`—Attach a serial line network interface.

SYNOPSIS

```
sliplogin [loginname]
```

DESCRIPTION

`sliplogin` is used to turn the terminal line on standard input into a serial line IP SLIP link to a remote host. To do this, the program searches the file for an entry matching `loginname` (which defaults to the current login name if omitted). If a

matching entry is found, the line is configured appropriately for slip (8-bit transparent I/O) and converted to slip line discipline. Then a shell script is invoked to initialize the slip interface with the appropriate local and remote IP address, netmask, and so on.

The usual initialization script is `/etc/slip/slip.lgin`, but if particular hosts need special initialization, the file `/etc/slip/slip.login.loginname` will be executed instead if it exists. The script is invoked with the parameters

<code>slipunit</code>	The unit number of the slip interface assigned to this line, such as 0 for <code>s10</code> .
<code>speed</code>	The speed of the line.
<code>args</code>	The arguments from the entry, in order starting with <code>loginname</code> .

Only the superuser can attach a network interface. The interface is automatically detached when the other end hangs up or the `sliplogin` process dies. If the kernel slip module has been configured for it, all routes through that interface will also disappear at the same time. If there is other processing a site wants done upon hangup, the file `/etc/slip/slip.logout` or `/etc/slip/slip.logout.loginname` is executed if it exists. It is given the same arguments as the login script.

FORMAT OF `/etc/slip.hosts`

Comments (lines starting with a #) and blank lines are ignored. Other lines must start with a `loginname`, but the remaining arguments can be whatever is appropriate for the file that will be executed for that name. Arguments are separated by whitespace and follow normal `sh(1)` quoting conventions (however, `loginname` cannot be quoted). Usually, lines have the form `loginname local-address remote-address netmask opt-args local-address remote-address` are the IP hostnames or addresses of the local and remote ends of the slip line, and `netmask` is the appropriate IP netmask. These arguments are passed directly to `ifconfig(8)`. `opt-args` are optional arguments used to configure the line.

EXAMPLE

The normal use of `sliplogin` is to create an entry for each legal, remote slip site with `sliplogin` as the shell for that entry, such as

```
Sfoo:ikhuy6:2010:1:slip line to foo:/tmp:/usr/sbin/sliplogin.
```

(Our convention is to name the account used by remote host hostname as `shostname`.) Then an entry is added that looks like

```
Sfoo 'hostname' foo netmask
```

'hostname' will be evaluated by `sh` to the local hostname and `netmask` is the local host IP netmask.

Note that `sliplogin` must be `setuid` to root, and although it's not a security hole, moral defectives can use it to place terminal lines in an unusable state or deny access to legitimate users of a remote slip line. To prevent this, a site can create a group, say `slip`, that only the slip login accounts are put in and then make sure that `/sbin/sliplogin` is in group `slip` and mode `4550` (`setuid` root, only group `slip` can execute binary).

DIAGNOSTICS

`sliplogin` logs various information to the system log daemon, `syslogd(8)`, with a facility code of `daemon`. The messages are listed here, grouped by severity level.

Error Severity

<code>ioctl (TCGETS): reason</code>	A <code>TCGETS ioctl</code> to get the line parameters failed.
<code>ioctl (TCSETS): reason</code>	A <code>TCSETS ioctl</code> to set the line parameters failed.
<code>/etc/slip.hosts: reason</code>	The file could not be opened.
<code>access denied for user</code>	No entry for user was found in <code>/etc/slip/slip.hosts</code>

Notice Severity

"attaching slip unit" <code>unit</code> for <code>loginname</code> SLIP <code>unit</code>	Unit was successfully attached.

5 August 1991

swapon, swapoff

swapon, swapoff—Enable/disable devices and files for paging and swapping.

SYNOPSIS

```
/sbin/swapon -a
/sbin/swapon special file ...
/sbin/swapoff -a
/sbin/swapoff special file ...
```

DESCRIPTION

`swapon` is used to specify devices on which paging and swapping are to take place. Calls to `swapon` usually occur in the system multiuser initialization file `/etc/rc` making all swap devices available, so that the paging and swapping activity is interleaved across several devices and files.

Usually, the first form is used:

`-a` All devices marked as `sw` swap devices in `/etc/fstab` are made available.

`swapoff` disables swapping on the specified devices and files or on all swap entries in `/etc/fstab` when the `-a` flag is given.

SEE ALSO

swapon(2), swapoff(2), fstab(5), init(8), mkswap(8), rc(8), mount(8)

FILES

<code>/dev/hd[ab]?</code>	Standard paging devices
<code>/dev/sd[ab]?</code>	Standard (SCSI) paging devices
<code>/etc/fstab</code>	ASCII filesystem description table

HISTORY

The `swapon` command appeared in 4.0 BSD.

Linux 0.99, 27 November 1993

sync

sync—Flush Linux filesystem buffers.

SYNOPSIS

```
sync
```

DESCRIPTION

`sync` executes `sync(2)`, which flushes the filesystem buffers to disk. `sync` should be called before the processor is halted in an unusual manner (before causing a kernel panic when debugging new kernel code). In general, the processor should be halted using the `reboot(8)` or `halt(8)` commands, which attempt to put the system in a quiescent state before calling `sync(2)`.

From Linus: “Note that `sync` is only guaranteed to schedule the dirty blocks for writing: It can actually take a short time before all the blocks are finally written. If you are doing the `sync` with the expectation of killing the machine soon after, please take this into account and sleep for a few seconds. (The `reboot(8)` command takes these precautions.)”

Linux 0.99, 20 November 1993

syslogd

`syslogd`—Linux system logging utilities.

DESCRIPTION

`syslogd` provides two system utilities, which provide support for system logging and kernel message trapping. Support of both `inetd` and UNIX domain sockets enables this utility package to support both local and remote logging.

System logging is provided by a version of `syslogd` derived from the stock BSD sources. Support for kernel logging is provided by the `klogd` utility, which allows kernel logging to be conducted in either a stand-alone fashion or as a client of `syslogd`.

Although the `syslogd` sources have been heavily modified, a couple of notes are in order. First of all, there has been a systematic attempt to ensure that `syslogd` follows standard BSD behavior as its default. The second important concept to note is that this version of `syslogd` interacts transparently with the version of `syslog` found in the standard libraries. If a binary linked to the standard shared libraries fails to function correctly, we want an example of the anomalous behavior.

CONFIGURATION FILE SYNTAX DIFFERENCES

`syslogd` uses a slightly different syntax for its configuration file from that of the original BSD sources. Originally, all messages of a specific priority and above were forwarded to the log file.

For example, the following line caused all output from the daemon facilities to go into `/usr/adm/daemons`:

```
# Sample syslog.conf
daemon.debug /usr/adm/daemons
```

Under the new scheme, this behavior remains the same. The difference is the addition of two new wildcard specifiers: the asterisk (*) and the equals sign (=). The * specifies that all messages for the indicated facility are to be directed to the destination. Note that this behavior is degenerate with specifying a priority level of debug. Users have indicated that the asterisk notation is more intuitive.

The = wildcard is used to restrict logging to the specified priority class. This allows, for example, routing only debug messages to a particular logging source.

For example, the following line in `syslog.conf` directs debug messages from all sources to the `/usr/adm/debug` file:

```
# Sample syslog.conf
daemon.=debug /usr/adm/debug
```

This may take some acclimatization for those individuals used to the pure BSD behavior, but testers have indicated that this syntax is somewhat more flexible than the BSD behavior. Note that these changes should not affect standard `syslog.conf` files. You must specifically modify the configuration files to obtain the enhanced behavior.

SUPPORT FOR REMOTE LOGGING

These modifications provide network support to the `syslogd` facility. Network support means that messages can be forwarded from one node running `syslogd` to another node running `syslogd` where they will be actually logged to a disk file.

The strategy is to have `syslogd` listen on a UNIX domain socket for locally generated log messages. This behavior will allow `syslogd` to interoperate with the `syslog` found in the standard C library. At the same time, `syslogd` listens on the standard `syslog` port for messages forwarded from other hosts. To have this work correctly, the services files (typically found in `/usr/etc/inet`) must have the following entry:

```
syslog 514/udp
```

To cause messages to be forwarded to another host, replace the normal file line in the `syslog.conf` file with the name of the host to which the messages is to be sent prepended with an `@`.

For example, to forward all messages to a remote host, use the following `syslog.conf` entry:

```
# Sample syslogd configuration file to
# messages to a remote host forward all.
.* @hostname
```

To forward all kernel messages to a remote host, the configuration file is

```
# Sample configuration file to forward all kernel
# messages to a remote host.
kern.* @hostname
```

OUTPUT TO NAMED PIPES (FIFOS)

This version of `syslogd` has support for logging output to named pipes (FIFOs). A FIFO or named pipe can be used as a destination for log messages by prepending a `|` to the name of the file. This is handy for debugging. Note that the FIFO must be created with the `mkfifo` command before `syslogd` is started.

The following configuration file routes debug messages from the kernel to a FIFO:

```
# Sample configuration to route kernel debugging
# messages ONLY to /usr/adm/debug which is a
# named pipe.
kern.=debug | /usr/adm/debug
```

INSTALLATION CONCERNS

There is probably one important consideration when installing this version of `syslogd`. This version of `syslogd` is dependent on proper formatting of messages by the `syslog` function. The functioning of the `syslog` function in the shared libraries changed somewhere in the region of `libc.so.4.[2-4].n`. The specific change was to null-terminate the message before transmitting it to the `/dev/log` socket. Proper functioning of this version of `syslogd` is dependent on null-termination of the message.

This problem will typically manifest itself if old statically linked binaries are being used on the system. Binaries using old versions of the `syslog` function will cause empty lines to be logged, followed by the message with the first character in the message removed. Relinking these binaries to newer versions of the shared libraries will correct this problem.

SECURITY THREATS

There is the potential for the `syslogd` daemon to be used as a conduit for a denial of service attack. Thanks go to John Morrison (jmorrison@rflab.ee.ubc.ca) for alerting me to this potential. A rogue programmer could very easily flood the `syslogd` daemon with `syslog` messages resulting in the log files consuming all the remaining space on the filesystem.

Activating logging over the `inet` domain sockets will of course expose a system to risks outside of programs or individuals on the local machine.

Version 1.2 of the utility set will address this problem. In the meantime, there are a number of methods for protecting a machine:

1. Logging can be directed to an isolated or non-root filesystem, which, if filled, will not impair the machine.
2. The `ext2` filesystem can be used, which can be configured to limit a certain percentage of a filesystem to usage by root only. Note that this will require `syslogd` to be run as a non-root process. Also note that this will prevent usage of remote logging because `syslogd` will be unable to bind to the 514/UDP socket.
3. Disabling `inet` domain sockets will limit risk to the local machine.
4. Use Step 3 and if the problem persists and is not secondary to a rogue program or daemon, get a 3.5 foot (approximately 1 meter) length of sucker rod and have a chat with the user in question. A sucker rod is 3/4-, 7/8-, or 1-inch hardened steel rod, male threaded on each end. Its primary use in the oil industry in Western North Dakota and other locations is to pump-suck oil from oil wells. Secondary uses are for the construction of cattle feed lots and for dealing with the occasional recalcitrant or belligerent individual.

FILES

`/etc/syslog.conf`

BUGS

Primarily, security concerns will be addressed in version 1.2.

Version 1.1, 28 January 1994

syslogd

`syslogd`—Log systems messages.

SYNOPSIS

```
syslogd [-f config_file] [-m mark_interval] [-p log_socket]
```

DESCRIPTION

`syslogd` reads and logs messages to the system console, log files, and other machines or users as specified by its configuration file. The options are as follows:

- f Specify the pathname of an alternate configuration file; the default is `/etc/syslog.conf`.
- m Select the number of minutes between “mark” messages; the default is 20 minutes.
- p Specify the pathname of an alternate log socket; the default is `/dev/log`.

`syslogd` reads its configuration file when it starts up and whenever it receives a hangup signal. For information on the format of the configuration file, see `syslog.conf(5)`.

`syslogd` reads messages from the UNIX domain socket `/dev/log`, from an Internet domain socket specified in `/etc/services`, and from the special device `/dev/klog` (to read kernel messages).

`syslogd` creates the file `/var/run/syslog.pid` and stores its process ID there. This can be used to kill or reconfigure `syslogd`.

The message sent to `syslogd` should consist of a single line. The message can contain a priority code, which should be a preceding decimal number in angle braces, such as `<5>`. This priority code should map into the priorities defined in the include file `<sys/syslog.h>`.

FILES

<code>/etc/syslog.conf</code>	The configuration file
<code>/var/run/syslog.pid</code>	The process ID of current <code>syslogd</code>
<code>/dev/log</code>	Name of the UNIX domain datagram log socket
<code>/dev/klog</code>	The kernel log device

HISTORY

The `syslogd` command appeared in BSD 4.3.

BSD 4.2, 16 March 1991

talkd

`talkd`—Remote user communication server.

SYNOPSIS

`talkd`

DESCRIPTION

`talkd` is the server that notifies a user that someone else wants to initiate a conversation. It acts a repository of invitations, responding to requests by clients who want to rendezvous to hold a conversation. In normal operation, a client, the caller, initiates a rendezvous by sending a `CTL MSG` to the server of type `LOOK UP` (see `protocols/talkd.h`). This causes the server to search its invitation tables to check if an invitation currently exists for the caller (to speak to the callee specified in the message). If the lookup fails, the caller then sends an `ANNOUNCE` message, causing the server to broadcast an announcement on the callee’s login ports requesting contact. When the callee responds, the local server uses the recorded invitation to respond with the appropriate rendezvous address and the caller and callee client programs establish a stream connection through which the conversation takes place.

SEE ALSO

`talk(1)`, `write(1)`

HISTORY

The `talkd` command appeared in BSD 4.3.

BSD 4.3, 16 March 1991

telnetd

`telnetd`—DARPA Telnet protocol server.

SYNOPSIS

```
/etc/telnetd [-debug [port]] [-l][-D options][--D report]
[-D exercise][--D netdata] [-D ptydata]
```

DESCRIPTION

`telnetd` is a server that supports the DARPA standard Telnet virtual terminal protocol. `telnetd` is invoked by the Internet server (see `inetd(8)`), usually for requests to connect to the Telnet port as indicated by the `/etc/services` file (see `services(5)`). If desired the `-debug` can be used, to start up `telnetd` manually, instead of through `inetd(8)`. If started up this way, `port` may be specified to run `telnetd` on an alternate TCP port number.

The `-D` option can be used for debugging purposes. This allows Telnet to print debugging information to the connection, allowing the user to see what `telnetd` is doing. There are several modifiers: `options` prints information about the negotiation of Telnet options, `report` prints the options information, plus some additional information about what processing is going on, `netdata` displays the data stream received by `telnetd`, `ptydata` displays data written to the `pty`, and `exercise` has not been implemented yet.

`telnetd` operates by allocating a pseudo-terminal device (see `pty(4)`) for a client) and then creating a login process that has the slave side of the pseudo-terminal as `stdin`, `stdout`, and `stderr`. `telnetd` manipulates the master side of the pseudo-terminal, implementing the Telnet protocol and passing characters between the remote client and the login process.

When a Telnet session is started, `telnetd` sends Telnet options to the client side, indicating a willingness to do a remote echo of characters, to suppress go ahead, to do remote flow control, and to receive terminal type information, terminal speed information, and window size information from the remote client. If the remote client is willing, the remote terminal type is propagated in the environment of the created login process. The pseudo-terminal allocated to the client is configured to operate in cooked mode and with `XTABS` and `CRMOD` enabled (see `tty(4)`).

`telnetd` is willing to do echo, binary, suppress go ahead, and timing mark. `telnetd` is willing to have the remote client do linemode, binary, terminal type, terminal speed, window size, toggle flow control, environment, X display location, and suppress go ahead.

If the file `/etc/issue.net` is present, `telnetd` will show its contents before the login prompt of a Telnet session (see `issue.net(5)`).

SEE ALSO

`telnet(1)`, `issue.net(5)`

BUGS

Some Telnet commands are only partially implemented.

Because of bugs in the original 4.2 BSD `telnet(1)`, `telnetd` performs some dubious protocol exchanges to try to discover if the remote client is, in fact, a 4.2 BSD `telnet(1)`.

Binary mode has no common interpretation except between similar operating systems (UNIX, in this case).

The terminal type name received from the remote client is converted to lowercase. `telnetd` never sends Telnet go ahead commands.

20 April 1991

tftpd

tftpd—DARPA Trivial File Transfer Protocol server.

SYNOPSIS

```
tftpd [di rectory ...]
```

DESCRIPTION

tftpd is a server that supports the DARPA Trivial File Transfer Protocol. The TFTP server operates at the port indicated in the tftp service description; see `services(5)`. The server is usually started by `inetd(8)`.

The use of `tftpd(1)` does not require an account or password on the remote system. Due to the lack of authentication information, `tftpd` will allow only publicly readable files to be accessed. Files may be written only if they already exist and are publicly writable. Note that this extends the concept of public to include all users on all hosts that can be reached through the network; this may not be appropriate on all systems, and its implications should be considered before enabling the tftp service. The server should have the user ID with the lowest possible privilege.

SEE ALSO

`tftp(1)`, `inetd(8)`

HISTORY

The `tftpd` command appeared in BSD 4.2.

BSD 4.2, 13 May 1991

timed

timed—Time server daemon.

SYNOPSIS

```
timed [-M] [-t] [-d] [-i network] [-n network] [-F host1 host2 ...]
```

DESCRIPTION

timed is a time server daemon and is usually invoked at boot time from the `rc(8)` file. It synchronizes the host's time with the time of other machines in a local area network running `timed(8)`. These time servers will slow down the clocks of some machines and speed up the clocks of others to bring them to the average network time. The average network time is computed from measurements of clock differences using the ICMP timestamp request message.

The service provided by `timed` is based on a master-slave scheme. When `timed(8)` is started on a machine, it asks the master for the network time and sets the host's clock to that time. After that, it accepts synchronization messages periodically sent by the master and calls `adjtime(2)` to perform the needed corrections on the host's clock.

It also communicates with `date(1)` to set the date globally and with `timedc(8)`, a timed control program. If the machine running the master crashes, then the slaves elect a new master from among slaves running with the `-M` flag. A `timed` running without the `-M` or `-F` flags remains a slave. The `-t` flag enables `timed` to trace the messages it receives in the file `/var/log/timed.log`. Tracing can be turned on or off by the program `timedc(8)`. The `-d` flag is for debugging the daemon. It causes the program to not put itself into the background. Usually, `timed` checks for a master time server on each network

to which it is connected, except as modified by the options. It requests synchronization service from the first master server located. If permitted by the `-M` flag, it provides synchronization service on any attached networks on which no current master server is detected. Such a server propagates the time computed by the top-level master. The `-n` flag, followed by the name of a network that the host is connected to (see `networks(5)`), overrides the default choice of the network addresses made by the program. Each time the `-n` flag appears, that network name is added to a list of valid networks. All other networks are ignored. The `-i` flag, followed by the name of a network to which the host is connected (see `networks(5)`), overrides the default choice of the network addresses made by the program. Each time the `-i` flag appears, that network name is added to a list of networks to ignore. All other networks are used by the time daemon. The `-n` and `-i` flags are meaningless if used together.

`timed` checks for a master time server on each network to which it is connected, except as modified by the `-n` and `-i` options. If it finds masters on more than one network, it chooses one network on which to be a “slave” and then periodically checks the other networks to see if the masters there have disappeared.

One way to synchronize a group of machines is to use an NTP daemon to synchronize the clock of one machine to a distant standard or a radio receiver and `-F hostname` to tell its `timed` daemon to trust only itself.

Messages printed by the kernel on the system console occur with interrupts disabled. This means that the clock stops while they are printing. A machine with many disk or network hardware problems and consequent messages cannot keep good time by itself. Each message typically causes the clock to lose a dozen milliseconds. A time daemon can correct the result.

Messages in the system log about machines that failed to respond usually indicate machines that crashed or were turned off. Complaints about machines that failed to respond to initial time settings are often associated with “multi-homed” machines that looked for time masters on more than one network and eventually chose to become a slave on the other network.

WARNING

If two or more time daemons, whether `timed`, NTP, try to adjust the same clock, temporal chaos will result. If both this and another time daemon are run on the same machine, ensure that the `-F` flag is used, so that `timed` never attempts to adjust the local clock.

The protocol is based on UDP/IP broadcasts. All machines within the range of a broadcast that are using the TSP protocol must cooperate. There cannot be more than a single administrative domain using the `-F` flag among all machines reached by a broadcast packet. Failure to follow this rule is usually indicated by complaints concerning “untrusted” machines in the system log.

BSD 4.3, 11 May 1993

timedc

`timedc`—Timed control program.

SYNOPSIS

```
timedc [command] [argument ...]
```

DESCRIPTION

`timedc` is used to control the operation of the `timed(8)` program. It may be used to

- Measure the differences between machines' clocks
- Find the location where the master time server is running
- Enable or disable tracing of messages received by `timed`
- Perform various debugging actions

Without any arguments, `timedc` will prompt for commands from the standard input. If arguments are supplied, `timedc` interprets the first argument as a command and the remaining arguments as parameters to the command. The standard input may be redirected, causing `timedc` to read commands from a file. Commands may be abbreviated; recognized commands are

<code>? [command ...]</code>	
<code>help [command ...]</code>	Print a short description of each command specified in the argument list or, if no arguments are given, a list of the recognized commands.
<code>clockdiff host ...</code>	Compute the differences between the clock of the host machine and the clocks of the machines given as arguments.
<code>mstime [host ...]</code>	Show the master time server for specified hosts.
<code>trace {on off}</code>	Enable or disable the tracing of incoming messages to <code>timed</code> in the file.
<code>election host</code>	Asks the daemon on the target host to reset its "election" timers and to ensure that a time master has been elected.
<code>quit</code>	Exit from <code>timedc</code>

Other commands may be included for use in testing and debugging `timed`; the `help` command and the program source may be consulted for details.

FILES

`/var/log/timed.log` tracing file for `timed`
`/var/log/timed.masterlog` log file for master `timed`

SEE ALSO

DIAGNOSTICS

<code>?Ambiguous command</code>	Abbreviation matches more than one command
<code>?Invalid command</code>	No match found
<code>?Privileged command</code>	Command can be executed by root only

HISTORY

The `timedc` command appeared in BSD 4.3.

BSD 4.3, 11 May 1993

traceroute

`traceroute`—Print the route that packets take to the network host.

SYNOPSIS

```
traceroute [-m max_ttl] [-n] [-p port] [-q nqueries]
[-r] [-s src_addr] [-t tos] [-w waittime] host [packetsize]
```

DESCRIPTION

The Internet is a large and complex aggregation of network hardware, connected together by gateways. Tracking the route one's packets follow (or finding the miscreant gateway that's discarding your packets) can be difficult. `traceroute` utilizes the IP protocol time-to-live field and attempts to elicit an ICMP `TIME_EXCEEDED` response from each gateway along the path to some host.

The only mandatory parameter is the destination hostname or IP number. The default probe datagram length is 38 bytes, but this can be increased by specifying a packet size (in bytes) after the destination hostname.

Other options are

<code>-m maxttl</code>	Set the max time-to-live (max number of hops) used in outgoing probe packets. The default is 30 hops (the same default used for TCP connections).
<code>-n</code>	Print hop addresses numerically rather than symbolically and numerically (saves a nameserver address-to-name lookup for each gateway found on the path).
<code>-p port</code>	Set the base UDP port number used in probes (default is 33434). <code>traceroute</code> hopes that nothing is listening on UDP ports base to base + <code>n_hops</code> - 1 at the destination host (so an ICMP <code>PORT_UNREACHABLE</code> message will be returned to terminate the route tracing). If something is listening on a port in the default range, this option can be used to pick an unused port range.
<code>-q nqueries</code>	Set the number of probes per <code>ttl</code> to <code>nqueries</code> (default is three probes).
<code>-r</code>	Bypass the normal routing tables and send directly to a host on an attached network. If the host is not on a directly attached network, an error is returned. This option can be used to ping a local host through an interface that has no route through it (for example, after the interface was dropped by <code>routed(8)</code>).
<code>-s src_addr</code>	Use the following IP address (which must be given as an IP number, not a hostname) as the source address in outgoing probe packets. On hosts with more than one IP address, this option can be used to force the source address to be something other than the IP address of the interface the probe packet is sent on. If the IP address is not one of this machine's interface addresses, an error is returned and nothing is sent.
<code>-t tos</code>	Set the type-of-service in probe packets to the following value (default zero). The value must be a decimal integer in the range 0 to 255. This option can be used to see if different types of service result in different paths. (If you are not running a BSD 4.3 tahoe or later system, this may be academic because the normal network services such as Telnet and FTP don't let you control the TOS). Not all values of TOS are legal or meaningful; see the IP spec for definitions. Useful values are probably (low delay) and (high throughput).
<code>-v</code>	Verbose output. Received ICMP packets other than <code>TIME_EXCEEDED</code> and <code>UNREACHABLES</code> are listed.
<code>-w</code>	Set the time (in seconds) to wait for a response to a probe (default is 3 seconds).

This program attempts to trace the route an IP packet would follow to some Internet host by launching UDP probe packets with a small `ttl` (time to live) and then listening for an ICMP "time exceeded" reply from a gateway. We start our probes with a `ttl` of one and increase by one until we get an ICMP "port unreachable" (which means we got to "host") or hit a max (which defaults to 30 hops and can be changed with the `-m` flag). Three probes (changed with the `-q` flag) are sent at each `ttl` setting and a line is printed showing the `ttl`, address of the gateway, and round-trip time of each probe. If the probe answers come from different gateways, the address of each responding system will be printed. If there is no response within a three second time-out interval (changed with the `-w` flag), a * is printed for that probe.

We don't want the destination host to process the UDP probe packets, so the destination port is set to an unlikely value (if some clod on the destination is using that value, it can be changed with the `-p` flag).

A sample use and output might be

```
[yak 71]% traceroute nis.nsf.net.
traceroute to nis.nsf.net (35.1.1.48), 30 hops max,
 56 byte packet
 1 helios.ee.lbl.gov (128.3.112.1) 19 ms 19 ms 0 ms
 2 lilac-dmc.Berkeley.EDU (128.32.216.1) 39 ms 39 ms 19 ms
 3 lilac-dmc.Berkeley.EDU (128.32.216.1) 39 ms 39 ms 19 ms
 4 ccngw-ner-cc.Berkeley.EDU (128.32.136.23) 39 ms 40 ms 39 ms
 5 ccn-nerif22.Berkeley.EDU (128.32.168.22) 39 ms 39 ms 39 ms
 6 128.32.197.4 (128.32.197.4) 40 ms 59 ms 59 ms
 7 131.119.2.5 (131.119.2.5) 59 ms 59 ms 59 ms
 8 129.140.70.13 (129.140.70.13) 99 ms 99 ms 80 ms
 9 129.140.71.6 (129.140.71.6) 139 ms 239 ms 319 ms
10 129.140.81.7 (129.140.81.7) 220 ms 199 ms 199 ms
11 nic.merit.edu (35.1.1.48) 239 ms 239 ms 239 ms
```

Note that Lines 2 and 3 are the same. This is due to a buggy kernel on the second hop system—`lbl.csam.arpa`—that forwards packets with a zero `ttl` (a bug in the distributed version of 4.3 BSD). Note that you have to guess what path the packets are taking cross-country because the NSFNet (129.140) doesn't supply address-to-name translations for its NSSs.

A more interesting example is

```
[yak 72]% traceroute allspice.lcs.mit.edu.
traceroute to allspice.lcs.mit.edu (18.26.0.115), 30 hops max
 1 helios.ee.lbl.gov (128.3.112.1) 0 ms 0 ms 0 ms

```

Note that the gateways 12, 14, 15, 16, and 17 hop away. Either don't send ICMP "time exceeded" messages or send them with a `ttl` too small to reach us. Lines 14–17 are running the MIT C Gateway code that doesn't send "time exceeded"s. God only knows what's going on with 12.

The silent gateway 12 may be the result of a bug in the 4.[23] BSD network code (and its derivatives): `4.x (x <= 3)` sends an unreachable message using whatever `ttl` remains in the original datagram. Because for gateways the remaining `ttl` is zero, the ICMP "time exceeded" is guaranteed to not make it back to us. The behavior of this bug is slightly more interesting when it appears on the destination system:

```
 1 helios.ee.lbl.gov (128.3.112.1) 0 ms 0 ms 0 ms
 2 lilac-dmc.Berkeley.EDU (128.32.216.1) 39 ms 19 ms 39 ms
 3 lilac-dmc.Berkeley.EDU (128.32.216.1) 19 ms 39 ms 19 ms
 4 ccngw-ner-cc.Berkeley.EDU (128.32.136.23) 39 ms 40 ms 19 ms
 5 ccn-nerif35.Berkeley.EDU (128.32.168.35) 39 ms 39 ms 39 ms
 6 csgw.Berkeley.EDU (128.32.133.254) 39 ms 59 ms 39 ms
 7 ***
 8 ***
```

```

9  ***
10 * * *
11 * * *
12 * * *
13 rip.Berkeley.EDU (128.32.131.22)  59 ms !  39 ms !  39 ms
!
```

Notice that there are 12 “gateways” (13 is the final destination) and exactly the last half of them are “missing.” What’s really happening is that rip (a Sun-3 running Sun OS3.5) is using the `ttl` from our arriving datagram as the `ttl` in its ICMP reply. The reply will time out on the return path (with no notice sent to anyone because ICMPs aren’t sent for ICMPs) until we probe with a `ttl` that’s at least twice the path length. That is, rip is really only seven hops away. A reply that returns with a `ttl` of 1 is a clue this problem exists. `traceroute` prints a `!` after the time if the `ttl` is less than or equal to 1. Because vendors ship a lot of obsolete (DEC Ultrix, Sun 3.x) or non-standard HPUX software, expect to see this problem frequently or take care picking the target host of your probes. Other possible annotations after the time are `!H`, `!N`, `!P` (got a host, network, or protocol unreachable), `!S`, or `!F` (source route failed or fragmentation needed—neither of these should ever occur and the associated gateway is busted if you see one). If almost all the probes result in some kind of unreachable, `traceroute` will give up and exit.

This program is intended for use in network testing, measurement, and management. It should be used primarily for manual fault isolation. Because of the load it could impose on the network, it is unwise to use `traceroute` during normal operations or from automated scripts.

AUTHOR

Implemented by Van Jacobson from a suggestion by Steve Deering. Debugged by a cast of thousands with particularly cogent suggestions or fixes from C. Philip Wood, Tim Seaver, and Ken Adelman.

tune2fs

`tune2fs`—Adjust tunable filesystem parameters on second extended filesystems.

SYNOPSIS

```

tune2fs [ -l ] [ -c max-mount-counts ] [ -e errors-behavior ]
[ -i interval-between-checks ] [ -m reserved-blocks-percentage ]
[ -r reserved-blocks-count ] [ -u user ] [ -g group ] device
```

DESCRIPTION

`tune2fs` adjusts tunable filesystem parameters on a Linux second extended filesystem.

Never use `tune2fs` on a read/write mounted filesystem to change parameters!

OPTIONS

<code>-c max-mount-counts</code>	Adjust the maximal mounts count between two filesystem checks.
<code>-e errors-behavior</code>	Change the behavior of the kernel code when errors are detected. <code>errors-behavior</code> can be one of the following:
<code>continue</code>	Continue normal execution.
<code>remount-ro</code>	Remount the filesystem read-only.
<code>panic</code>	Causes a kernel panic.

-g group	Set the user group that can benefit from the reserved blocks. <code>group</code> can be a numerical GID or a group name.
-i interval -between-checks[d m w]	Adjust the maximal time between two filesystem checks. No postfix or <code>d</code> results in days, <code>m</code> in months, and <code>w</code> in weeks. A value of <code>0</code> will disable the time-dependent checking.
-l	List the contents of the filesystem superblock.
-m reserved-blocks-percentage	Adjust the reserved blocks percentage on the given device.
-r reserved-blocks-count	Adjust the reserved blocks count on the given device.
-u user	Set the user who can benefit from the reserved blocks. <code>user</code> can be a numerical UID or a username.

BUGS

We didn't find any bugs. Perhaps there are bugs, but it's unlikely.

WARNING

Use this utility at your own risk. You're modifying filesystems.

AUTHOR

`tune2fs` was written by Remy Card (`card@masi.ibp.fr`), the developer and maintainer of the `ext2` filesystem. `tune2fs` uses the `ext2fs` library written by Theodore T'so (`tytso@mit.edu`). This manual page was written by Christian Kutz (`chk@data-hh.Hanse.DE`). Time-dependent checking was added by Uwe Ohse (`uwe@tirka.gun.de`).

AVAILABILITY

`tune2fs` is available for anonymous FTP from `ftp.ibp.fr` and `tsx-11.mit.edu` in `/pub/linux/packages/ext2fs`.

tunelp

`tunelp`—Set various parameters for the `lp` device.

SYNOPSIS

```
tunelp device [-i IRQ] [-t TIME] [-c CHARS]
| -w WAIT | -a [on|off] | -o [on|off] | -C [on|off]
| -r | -s | -q [on|off] ]
```

DESCRIPTION

`tunelp` sets several parameters for the `/dev/lp?` devices, for better performance (or for any performance at all, if your printer won't work without it...). Without parameters, `tunelp` tells whether the device is using interrupts, and if so, which one.

With parameters, `tunelp` sets the device characteristics accordingly. The parameters are as follows:

-i <IRQ>	The IRQ to use for the parallel port in question. If this is set to something nonzero, <code>-t</code> and <code>-c</code> have no effect. If your port does not use interrupts, this option will make printing stop. <code>tunelp -i 0</code> restores non-interrupt driven (polling) action, and your printer should work again. If your parallel port does support interrupts, interrupt-driven printing should be somewhat faster and efficient and will probably be desirable.
-t <TIME>	The amount of time in jiffies that the driver waits if the printer doesn't take a character for the number of tries dictated by the <code>-c</code> parameter. <code>10</code> is the default value. If you want the fastest possible printing and don't care about system load, you can set this to <code>0</code> . If

	you don't care how fast your printer goes or are printing text on a slow printer with a buffer, then 500 (5 seconds) should be fine and will give you very low system load. This value generally should be lower for printing graphics than text, by a factor of approximately 10, for best performance.
-c <CHARS>	The number of times to try to output a character to the printer before sleeping for -t <TIME>. It is the number of times around a loop that tries to send a character to the printer. 120 appears to be a good value for most printers. 250 is the default because there are some printers that require a wait this long, but feel free to change this. If you have a very fast printer like an HP Laserjet 4, a value of 10 might make more sense. If you have a really old printer, you can increase this.
	Setting -t <TIME> to 0 is equivalent to setting -c <CHARS> to infinity.
-w <WAIT>	The busy loop counter for the strobe signal. Although most printers appear to be able to deal with an extremely short strobe, some printers demand a longer one. Increasing this from the default 0 might make it possible to print with those printers. This can also make it possible to use longer cables.
-a [on off]	This is whether to abort on printer error; the default is not to. If you are sitting at your computer, you probably want to be able to see an error and fix it and have the printer go on printing. On the other hand, if you aren't, you might rather that your printer spooler find out that the printer isn't ready, quit trying, and send you mail about it. The choice is yours.
-o [on off]	This option is much like -a. It makes any open() of this device check to see that the device is online and not reporting any out-of-paper or other errors. This is the correct setting for most versions of lpd.
-C [on off]	This option adds extra ("careful") error checking. When this option is on, the printer driver will ensure that the printer is online and not reporting any out-of-paper or other errors before sending data. This is particularly useful for printers that usually appear to accept data when turned off.
-s	This option returns the current printer status, both as a decimal number from 0 to 255 and as a list of active flags. When this option is specified, -q off, turning off the display of the current IRQ, is implied.
	-o, -C, and -s all require a Linux kernel version of 1.1.76 or later.
-r	This option resets the port. It requires a Linux kernel version of 1.1.80 or later.
-q [on off]	This option sets printing the display of the current IRQ setting.

Cohesive Systems, 26 August 1992

update_state

update_state—Update system state.

SYNOPSIS

```
update_state
```

DESCRIPTION

update_state updates a bunch of system states. It takes a long time to execute and would be suitable for execution in a cron job.

Currently, update_state performs the following functions: updates the locate database (in /usr/lib/locate), updates the whatis database (in /usr/man, /usr/local/man, /usr/X386/man, and /usr/interviews/man), and updates the TeX ls-R cache file (in /usr/lib/texmf).

BUGS

The script expects things to be where the FSSTND says they are. For example, if you have `makewhatis(8)` in `/usr/lib`, where it is traditionally, then you lose, because it should be in `/usr/bin`.

uucico

uucico—UUCP file transfer daemon.

SYNOPSIS

uucico [options]

DESCRIPTION

The `uucico` daemon processes file transfer requests queued by `uucp(1)` and `uux(1)`. It is started when `uucp` or `uux` is run (unless they are given the `-r` option). It is also typically started periodically using entries in the `crontab` tables.

When invoked with `-r1`, `--master`, `-s`, `--system`, or `-S`, the daemon will place a call to a remote system, running in master mode. Otherwise, the daemon will start in slave mode, accepting a call from a remote system. Typically, a special login name will be set up for UUCP, which automatically invokes `uucico` when a call is made.

When `uucico` terminates, it invokes the `uuxqt(8)` daemon, unless the `-q` or `--nouuxqt` option is given; `uuxqt(8)` executes any work orders created by `uux(1)` on a remote system and any work orders created locally that have received remote files for which they were waiting.

If a call fails, `uucico` will usually refuse to retry the call until a certain (configurable) amount of time has passed. This may be overridden by the `-f`, `-force`, or `-S` option.

The `-l`, `--prompt`, `-e`, or `--loop` options may be used to force `uucico` to produce its own prompts of `login:` and `Password:`. When another daemon calls in, it will see these prompts and log in as usual. The login name and password are usually checked against a separate list kept specially for `uucico` rather than the `/etc/passwd` file; it is possible on some systems to direct `uucico` to use the `/etc/passwd` file. The `-l` or `-prompt` option will prompt once and then exit; in this mode, the UUCP administrator or the superuser may use the `-u` or `-login` option to force a login name, in which case `uucico` will not prompt for one. The `-e` or `-loop` option will prompt again after the first session is over; in this mode, `uucico` will permanently control a port.

If `uucico` receives a `SIGQUIT`, `SIGTERM`, or `SIGPIPE` signal, it will cleanly abort any current conversation with a remote system and exit. If it receives a `SIGHUP` signal, it will abort any current conversation, but will continue to place calls to (if invoked with `-r1` or `--master`) and accept calls from (if invoked with `-e` or `--loop`) other systems. If it receives a `SIGINT` signal, it will finish the current conversation but will not place or accept any more calls.

OPTIONS

The following options may be given to `uucico`:

<code>-r1</code> , <code>--master</code>	Start in master mode (call out to a system); implied by <code>-s</code> , <code>--system</code> , or <code>-S</code> . If no system is specified, call any system for which work is waiting to be done.
<code>-r0</code> , <code>--slave</code>	Start in slave mode. This is the default.
<code>-s system</code> , <code>--system system</code>	Call the named system.

-S system	Call the named system, ignoring any required wait. This is equivalent to <code>-s system -f</code> .
-f, ---force	Ignore any required wait for any systems to be called.
-l, ---prompt	Prompt for login name and password using <code>login:</code> and <code>Password:.</code> This allows <code>uucico</code> to be easily run from <code>inetd(8)</code> . The login name and password are checked against the UUCP password file, which probably has no connection to the file <code>/etc/passwd</code> . The <code>--login</code> option may be used to force a login name, in which case <code>uucico</code> will only prompt for a password.
-p port, ---port port	Specify a port to call out on or to listen to.
-e, ---loop	Enter endless loop of login/password prompts and slave mode daemon execution. The program will not stop by itself; you must use <code>kill(1)</code> to shut it down.
-w, ---wait	After calling out (to a particular system when <code>-s, --system,</code> or <code>-S</code> is specified or to all systems that have work when just <code>-r1</code> or <code>--master</code> is specified), begin an endless loop as with <code>--loop</code> .
-q, ---nouuxqt	Do not start the <code>uuxqt(8)</code> daemon when finished.
-c, ---quiet	If no calls are permitted at this time, then don't make the call, but also do not put an error message in the log file and do not update the system status (as reported by <code>uustat(1)</code>). This can be convenient for automated polling scripts, which may want to simply attempt to call every system rather than worry about which particular systems may be called at the moment. This option also suppresses the log message indicating that there is no work to be done.
-C, ---ifwork	Only call the system named by <code>-s, --system,</code> or <code>-S</code> if there is work for that system.
-D, ---nodetach	Do not detach from the controlling terminal. Normally, <code>uucico</code> detaches from the terminal before each call out to another system and before invoking <code>uuxqt</code> . This option prevents this.
-u name, ---login name	Set the login name to use instead of that of the invoking user. This option may only be used by the UUCP administrator or the superuser. If used with <code>--prompt</code> , this will cause <code>uucico</code> to prompt only for the password, not the login name.
-z, ---try-next	If a call fails after the remote system is reached, try the next alternate rather than simply exiting.
-i type, ---stdin type	Set the type of port to use when using standard input. The only support port type is TLI, and this is only available on machines that support the TLI networking interface. Specifying <code>-iTLI</code> causes <code>uucico</code> to use TLI calls to perform I/O.
-x type, -X type, ---debug type	Turn on particular debugging types. The following types are recognized: <code>abnormal, chat, handshake, uucp-proto, proto, port, config, spooldir, execute, incoming, outgoing</code> . Multiple types may be given, separated by commas, and the <code>--debug</code> option may appear multiple times. A number may also be given, which will turn on that many types from the foregoing list; for example, <code>--debug 2</code> is equivalent to <code>--debug abnormal,chat</code> . The debugging output is sent to the debugging file, usually one of <code>/usr/spool/uucp/Debug, /usr/spool/uucp/DEBUG, or /usr/spool/uucp/.Admin/audit.local</code> .
-I file, ---config file	Set configuration file to use. This option may not be available, depending on how <code>uucico</code> was compiled.
-v, ---version	Report version information and exit.
--help	Print a help message and exit.
-u login	This option is ignored. It is only included because some versions of <code>uucpd</code> invoke <code>uucico</code> with it.

FILES

The filenames may be changed at compilation time or by the configuration file, so these are only approximations:

<code>/usr/lib/uucp/config</code>	Configuration file.
<code>/usr/lib/uucp/passwd</code>	Default UUCP password file.

/usr/spool/uucp	UUCP spool directory.
/usr/spool/uucp/Log	UUCP log file.
/usr/spool/uucppublic	Default UUCP public directory.
/usr/spool/uucp/Debug	Debugging file.

vmstat

vmstat—Report virtual memory statistics.

SYNOPSIS

```
vmstat [ -n ] [ delay [ count ] ]
```

DESCRIPTION

vmstat reports information about processes, memory, paging, block IO, traps, and CPU activity.

The first report produced gives averages since the last reboot. Additional reports give information on a sampling period of length delay. The process and memory reports are instantaneous in either case.

OPTIONS

The `-n` switch causes the header to be displayed only once rather than periodically.

`del ay` is the delay between updates in seconds. If no delay is specified, only one report is printed with the average values since boot.

`count` is the number of updates. If no count is specified and `del ay` is defined, `count` defaults to infinity.

FIELD DESCRIPTIONS

Procs

r	The number of processes waiting for runtime.
b	The number of processes in uninterruptible sleep.
w	The number of processes swapped out but otherwise runnable. This field is calculated, but Linux never desperation swaps.

Memory

swpd	The amount of virtual memory used (KB).
free	The amount of idle memory (KB).
buff	The amount of memory used as buffers (KB).

Swap

si	Amount of memory swapped in from disk (KB/s).
so	Amount of memory swapped to disk (KB/s).

IO

bi	Blocks sent to a block device (blocks/s).
bo	Blocks received from a block device (blocks/s).

System

in	The number of interrupts per second, including the clock.
cs	The number of context switches per second.

CPU (These are percentages of total CPU time.)

us	User time.
sy	System time.
id	Idle time.

NOTES

`vmstat` does not require special permissions.

These reports are intended to help identify system bottlenecks. Linux `vmstat` does not count itself as a running process.

All Linux blocks are currently 1KB, except for CD-ROM blocks, which are 2KB.

FILES

`/proc/meminfo`
`/proc/stat`
`/proc/*/stat`

SEE ALSO

`ps(1)`, `top(1)`, `free(1)`

BUGS

`vmstat` does not tabulate the block IO per device or count the number of system calls.

vipw

`vipw`—Edit the password file.

SYNOPSIS

`vipw`

DESCRIPTION

`vipw` edits the password file after setting the appropriate locks and does any necessary processing after the password file is unlocked. If the password file is already locked for editing by another user, `vipw` will ask you to try again later. The default editor for `vipw` is `vi(1)`.

ENVIRONMENT

If the following environment variable exists, it will be utilized by `vipw`:

`EDITOR` The editor specified by the string. `EDITOR` will be invoked instead of the default editor `vi(1)`.

SEE ALSO

`passwd(1)`, `vi(1)`, `passwd(5)`

HISTORY

The `vipw` command appeared in BSD 4.0.

BSD 4, 16 March 1991

zdump

`zdump`—Time zone dumper.

SYNOPSIS

```
zdump [ -v ] [-c cutoffyear ] [ zonename ... ]
```

DESCRIPTION

`zdump` prints the current time in each `zonename` named on the command line.

These options are available:

<code>-v</code>	For each <code>zonename</code> on the command line, print the current time, the time at the lowest possible time value, the time one day after the lowest possible time value, the times both one second before and exactly at each detected time discontinuity, the time at one day less than the highest possible time value, and the time at the highest possible time value. Each line ends with <code>isdst=1</code> if the given time is Daylight Saving Time or <code>isdst=0</code> otherwise.
<code>-c cutoffyear</code>	Cut off the verbose output near the start of the given year.

SEE ALSO

`newctime(3)`, `tzfile(5)`, `zic(8)`

zic

`zic`—Time zone compiler.

SYNOPSIS

```
zic [ -v ] [-d directory ] [-l local time ] [-p posixrules ]
[-L leapsecondfilename ] [-s ] [ -y command ] [filename ... ]
```

DESCRIPTION

`zic` reads text from the files named on the command line and creates the time conversion information files specified in this input. If a filename is `-`, the standard input is read.

These options are available:

<code>-d directory</code>	Create time conversion information files in the named directory rather than in the standard directory named below.
---------------------------	--

-l <i>timezone</i>	Use the given time zone as local time. <i>zic</i> will act as if the input contained a link line of the form. Link <i>timezone</i> localtime.
-p <i>timezone</i>	Use the given time zone's rules when handling POSIX-format time zone environment variables. <i>zic</i> will act as if the input contained a link line of the form. Link <i>timezone</i> posixrules.
-L <i>leapsecondfilename</i>	Read leap second information from the file with the given name. If this option is not used, no leap second information appears in output files.
-v	Complain if a year that appears in a data file is outside the range of years representable by <i>time(2)</i> values.
-s	Limit time values stored in output files to values that are the same whether they're taken to be signed or unsigned. You can use this option to generate SVVS-compatible files.
-y <i>command</i>	Use the given command rather than <i>yearistype</i> when checking year types.

Input lines are made up of fields. Fields are separated from one another by any number of whitespace characters. Leading and trailing whitespace on input lines is ignored. An unquoted sharp character (#) in the input introduces a comment that extends to the end of the line the sharp character appears on. Whitespace characters and sharp characters may be enclosed in double quotes (") if they're to be used as part of a field. Any line that is blank (after comment stripping) is ignored. Non-blank lines are expected to be of one of three types: rule lines, zone lines, and link lines.

A rule line has the form

```
Rule NAME FROM TO TYPE IN ON AT SAVE LETTER/S
```

For example:

```
Rule US 1967 1973 - Apr lastSun 2:00 1:00 D
```

The fields that make up a rule line are

NAME	Gives the (arbitrary) name of the set of rules this rule is part of.
FROM	Gives the first year in which the rule applies. Any integer year can be supplied; the Gregorian calendar is assumed. The word <i>minimum</i> (or an abbreviation) means the minimum year representable as an integer. The word <i>maximum</i> (or an abbreviation) means the maximum year representable as an integer. Rules can describe times that are not representable as time values, with the unrepresentable times ignored; this allows rules to be portable among hosts with differing time value types.
TO	Gives the final year in which the rule applies. In addition to minimum and maximum, the word <i>only</i> (or an abbreviation) may be used to repeat the value of the FROM field.
TYPE	Gives the type of year in which the rule applies. If TYPE is -, the rule applies in all years between FROM and TO inclusive. If TYPE is something else, then <i>zic</i> executes the command <i>yearistype year type</i> to check the type of a year. An exit status of zero is taken to mean that the year is of the given type; an exit status of one is taken to mean that the year is not of the given type.
IN	Names the month in which the rule takes effect. Month names may be abbreviated.
ON	Gives the day on which the rule takes effect. Recognized forms include <ul style="list-style-type: none"> 5 The fifth of the month lastSun The last Sunday in the month lastMon The last Monday in the month Sun>=8 First Sunday on or after the eighth Sun<=25 Last Sunday on or before the 25th Names of days of the week may be abbreviated or spelled out in full. Note that there must be no spaces within the ON field.

AT	Gives the time of day at which the rule takes effect. Recognized forms include 2 Time in hours 2:00 Time in hours and minutes 15:00 24-hour format time (for times after noon) 1:28:14 Time in hours, minutes, and seconds Any of these forms may be followed by the letter <i>w</i> if the given time is local wall clock time, <i>s</i> if the given time is local standard time, or <i>u</i> (or <i>g</i> or <i>z</i>) if the given time is universal time; in the absence of an indicator, wall clock time is assumed.
SAVE	Gives the amount of time to be added to local standard time when the rule is in effect. This field has the same format as the AT field (although, of course, the <i>w</i> and <i>s</i> suffixes are not used).
LETTER/S	Gives the variable part (for example, the <i>s</i> or <i>D</i> in EST or EDT) of time-zone abbreviations to be used when this rule is in effect. If this field is -, the variable part is null.

A zone line has the form

Zone NAME GMTOFF RULES/SAVE FORMAT [UNTIL]

For example:

Zone Australia/Adelaide 9:30 Aus CST 1971 Oct 31 2:00

The fields that make up a zone line are

NAME	The name of the time zone. This is the name used in creating the time conversion information file for the zone.
GMTOFF	The amount of time to add to GMT to get standard time in this zone. This field has the same format as the AT and SAVE fields of rule lines; begin the field with a minus sign if time must be subtracted from GMT.
RULES/SAVE	The name of the rules that apply in the time zone or, alternately, an amount of time to add to local standard time. If this field is -, standard time always applies in the time zone.
FORMAT	The format for time zone abbreviations in this time zone. The pair of characters %s is used to show where the variable part of the time-zone abbreviation goes. Alternately, a slash (/) separates standard and daylight abbreviations.
UNTIL	The time at which the GMT offset or the rules change for a location. It is specified as a year, a month, a day, and a time of day. If this is specified, the time-zone information is generated from the given GMT offset and rule change until the time specified. The next line must be a continuation line; this has the same form as a zone line except that the string Zone and the name are omitted because the continuation line will place information starting at the time specified as the UNTIL field in the previous line in the file used by the previous line. Continuation lines may contain an UNTIL field, just as zone lines do, indicating that the next line is a further continuation.

A link line has the form

Link LINK-FROM LINK-TO

For example:

Link US/Eastern EST5EDT

The LINK-FROM field should appear as the NAME field in some zone line; the LINK-TO field is used as an alternate name for that zone.

Except for continuation lines, lines may appear in any order in the input.

Lines in the file that describe leap seconds have the following form:

Leap YEAR MONTH DAY HH:MM:SS CORR R/S

For example:

Leap 1974 Dec 31 23:59:60 + S

The YEAR, MONTH, DAY, and HH:MM:SS fields tell when the leap second happened. The CORR field should be + if a second was added or - if a second was skipped. The R/S field should be (an abbreviation of) Stationary if the leap second time given by the other fields should be interpreted as GMT or (an abbreviation of) Rolling if the leap second time given by the other fields should be interpreted as local wall clock time.

NOTE

For areas with more than two types of local time, you may need to use local standard time in the AT field of the earliest transition time's rule to ensure that the earliest transition time recorded in the compiled file is correct.

FILE

/usr/local/etc/zoneinfo standard directory used for created files.

Guide**

add_timer, del_timer, init_timer

add_timer, del_timer, init_timer—Manage event timers.

SYNOPSIS

```
#include <asm/param.h>
#include <linux/timer.h>
extern void add_timer(struct timer_list * timer);
extern int del_timer(struct timer_list * timer);
extern inline void init_timer(struct timer_list * timer);
```

DESCRIPTION

add_timer schedules an event, adding it to a linked list of events maintained by the kernel. del_timer deletes a scheduled event. timer points to a

```
struct timer_list {
struct timer_list *next;
struct timer_list *prev;
unsigned long expires;
unsigned long data;
void (*function)(unsigned long);
};
```

init_timer sets next and prev to NULL. This is required for the argument of add_timer. expires is the desired duration of the timer in jiffies, where there are HZ (typically 100) jiffies per second. When the timer expires, function is called with data as its argument. It is the responsibility of function to delete the event. If the same function is managing several timers, the argument can be used to distinguish which one expired.

RETURN VALUE

del_timer returns zero on error—if next or prev are not NULL, but the timer was not found. del_timer also sets expires to the time remaining before the timer expires and sets next and prev to NULL. Thus, calling del_timer followed immediately by add_timer is a no-op provided a kernel tick does not occur between the two calls.

adjust_clock

adjust_clock—Adjusts startup time counter to tick in GMT.

SYNOPSIS

```
linux/kernel/sys.c
void adjust_clock();
```

DESCRIPTION

This routine adjusts the startup time by adding the time zone information to it. The goal is to get the startup time ticking in GMT time.

NOTES

This routine is called from settimeofday(2) when the time-zone information is first set.

Theodore T'so (tytso@mit.edu)

SEE ALSO

settimeofday(2)

Linux 0.99.10, 7 July 1993

ctrl_alt_del

ctrl_alt_del—Routes the keyboard interrupt Ctrl+Alt+Del key sequence.

SYNOPSIS

```
linux/kernel/sys.c
void ctrl_alt_del(void);
```

DESCRIPTION

This simple routine tests the variable `C_A_D` for a true/false condition. If it is true, a hard reset is done by the system. Otherwise, a signal `SIGINT` is sent to the process with the process ID 1, usually a program called `init`.

WARNINGS

This routine is in interrupt mode. It cannot `sync()` your system. Data loss may occur. It is recommended that you configure your system to send a signal to `init`, where you can control the shutdown.

NOTES

The default of this function is to do hard resets immediately.

file_table

file_table—Detailed description of the table and table entry.

SYNOPSIS

```
From #include <linux/fs.h>

struct file {
mode_t f_mode;
dev_t f_rdev; /* needed for /dev/tty */
off_t f_pos;
unsigned short f_flags;
unsigned short f_count;
unsigned short f_reada;
struct file *f_next, *f_prev;
struct inode *f_inode;
```

```
struct file_operations *f_op;
};
```

From `linux/fs/file_table.c`

```
struct file *first_file;
int nr_files = 0;
```

DESCRIPTION

The file table is fundamentally important to any UNIX system. It is where all open files (Linux includes closed files as well) are stored and managed by the kernel. For Linux, you can hardly do anything without referencing it in some way.

Linux stores its file table as a double circular linked list. The root pointer to the “head” of this list is `first_file`. Also, a count of how many entries are in the file table is maintained, called `nr_files`. Under this scheme, the file table for Linux could be as large as memory could hold. Unfortunately, this would be unmanageable in most cases. Your computer would be in the kernel most of the time when processes are more important. To keep this from happening, `nr_files` is tested against `NR_FILE` to limit the number of file table entries.

UNDERSTANDING THE STRUCTURE OF THE FILE TABLE

The file table is organized as a double circular linked list. Imagine a circle of people with everyone facing the same direction. Each person is facing so that one arm is in the circle and the other arm is outside the circle. Now, if each person put his or her right hand on the shoulder of the person in front of him or her and if each person touched the person behind him or her with his or her left hand. You have formed two circles of arms, one inside and the other outside. The right arms represent pointers to the next entry (or person). The left arms represent pointers to the previous entry (or person).

THE FILE STRUCTURE, A FILE TABLE ENTRY

At first glance, a table entry looks quite simple. An entry contains how a file was opened, what `tty` device, a reference count, pointers to other entries, pointer to `v-node` (the `vfs` `i-node`) filesystem-specific `i-node` information, and so on.

<code>f_mode</code>	After ANDing with <code>O_ACCMODE</code> , this is what bits 0 and 1 mean:
00	No permissions needed
01	Read-permission
10	Write-permission
11	Read-write
<code>f_rdev</code>	It is used only with <code>tty</code> lines. It contains the major and minor numbers of the <code>tty</code> device.
<code>f_pos</code>	The current position in a file, if meaningful.
<code>f_flags</code>	Storage for the flags from <code>open()</code> and <code>fcntl()</code>
<code>f_count</code>	Reference counter
<code>f_reada</code>	This is a Boolean variable where <code>True</code> means that an actual read is needed.
<code>f_next, f_prev</code>	Pointers to other entries
<code>f_inode</code>	Pointer to <code>v-node</code> and filesystem-specific <code>i-node</code> information
<code>f_op</code>	Pointer to a file’s operations

file_table_init

`file_table_init`—Initializes the file table in the kernel.

SYNOPSIS

```
linux/fs/file_table.c unsigned long file_table_init(
unsigned long start, unsigned long end);
```

DESCRIPTION

This routine is called from `kernel_start()` in `linux/init/main.c`. It sets `first_file`, a struct file pointer, to `NULL`. This is the head of the linked list of open files maintained in the kernel, the infamous file table in all UNIXs.

RETURN VALUE

Returns `start`.

NOTES

Because this is part of the kernel's startup routine, it has the option to allocate memory, in kernel space, for itself. It does not need to do this and returns the new start of memory for the next initializing section. In this case, `start` is returned unmodified.

Linux 0.99.10, 9 July 1993

filesystems

`filesystems`—Details the table of configured filesystems.

SYNOPSIS

```
linux/fs/filesystems.c
```

```
From #include <linux/fs.h>
```

```
struct file_system_type {
struct super_block *(*read_super) (struct super_block *, void *, int);
char *name;
int requires_dev;
};
```

DESCRIPTION

This source code makes a data structure call `file_systems[]`, which contains all the configured filesystems for the kernel. It is used primarily in `linux/fs/super.c` for many of the mounting of filesystems functions.

THE MEANINGS

This first member, in `struct file_system_type`, is a function pointer to a routine that will read in the `super_block`. A `super_block` generically means an `i-node` or special place on the device where information about the overall filesystem is stored.

The `name` is just the string representation of the name of a specific filesystem, such as `ext2` or `minix`.

The final member, `int_requires_dev`, is a Boolean value. If it is `True`, then the filesystem requires a block device. For `False`, it is unclear what happens, but an unnamed device is used, such as `proc` and `nfs`.

get_empty_filp

`get_empty_filp`—Fetches an unreferenced entry from the file table.

SYNOPSIS

```
linux/fs/file table.c
struct file *get_empty_filp(void);
```

DESCRIPTION

This routine will seek out an entry that is not being referenced by any processes. If none are found, then it will add new entries to the file table, minimum of `NR_FILE` entries.

NOTES

Due to `grow_files()`, a whole page of entries is created at one time. This may make more than `NR_FILE` entries. Also when an unreferenced entry is found, it is moved to the “end” of the file table. This heuristic is used to speed up finding unreferenced entries.

RETURN VALUE

`NULL`—No entries were found and the file table is full.

Returns a pointer to the entry in the file table.

`grow_files(9)`*Linux 0.99.10, 12 July 1993*

grow_files

`grow_files`—Adds entries to the file table.

SYNOPSIS

```
linux/fs/file table.c
void grow_files(void);
```

DESCRIPTION

This function adds entries to the file table. First, it allocates a page of memory. It fills the entire page with entries, adding each to the file table.

in_group_p

in_group_p—Searches group IDs for a match.

SYNOPSIS

```
linux/kernel/sys.c
int in_group_p(gid_t grp);
```

DESCRIPTION

Searches supplementary group IDs and the effective group ID for a match with `grp`.

RETURN VALUE

Returns `True` (1) if found; otherwise, `false` (0).

insert_file_free

insert_file_free—Adds a file entry into the file table.

SYNOPSIS

```
linux/fs/file_table.c
static void insert_file_free(struct file *file);
```

DESCRIPTION

This nightmare of pointers adds `file` into the file table with the root pointer at `file`. This is a building block of the file table management.

Linux 0.99.10

kernel_mktime

`kernel_mktime`—Convert startup `struct mktime` into the number of seconds since 00:00:00 January 1, 1970.

SYNOPSIS

```
linux/kernel/mktime.c
long kernel_mktime(struct mktime * time);
```

DESCRIPTION

This routine is called from `time_init(void)`, `linux/init/main.c`. `kernel_mktime()` converts `struct mktime` (initialized from CMOS) into an encoded long.

CONVERSION METHOD

First an array, `month[12]`, is created, holding how many seconds have passed to reach a peculiar month for a leap year. Next, it subtracts 70 from the current year, making 1970 the beginning year. It is math magic after this point; please look yourself. If you know why it does this, then send e-mail (see `nroff` source).

RETURN VALUE

Returns the encoded time in a long.

FILES

`linux/kernel/mktime.c` home of routine

NOTES

This routine is called only during startup of the kernel.

Historically, the value (encoded long) counts the number of seconds since the Epoch, which occurred at 00:00:00 January 1, 1970, and is called Coordinated Universal Time (UTC). In older manuals, this event is called Greenwich Mean Time (GMT).

WARNINGS

`kernel_mktime()` doesn't check to see if the year is greater than 1969. Be sure your CMOS is set correctly. It is customary to set on-board clocks to GMT and let processes who ask for the time to convert it to local time, if necessary.

RESTRICTIONS

For kernel use only.

AUTHOR

Linus Torvalds

Linux 0.99.10, 5 July 1993

proc_sel

`proc_sel`—Select a process by a criterion.

SYNOPSIS

```
linux/kernel/sys.c
#include <linux/resource.h>
static int proc_sel(struct task_struct *p, int which, int who);
```

DESCRIPTION

Compares a task `p` to supplied information or the current task in some aspect of priority. If `who` is zero, the comparison is task `p` and the current task. Otherwise, `who` and `*p` are the supplied information for the comparison.

OPTIONS

Valid values of `who` are:

<code>PRIO_PROCESS</code>	Compares process ID numbers. There is an exception here. If <code>who</code> is not zero and task <code>p</code> is the current task, then <code>True</code> is always returned.
<code>PRIO_PGRP</code>	Compares process group leader numbers.
<code>PRIO_USER</code>	Compares user ID numbers.

RETURN VALUE

Returns truth values (0, 1).

Linux 0.99.10, 7 July 1993

put_file_last

`put_file_last`—Moves a file to the “end” of the file table.

SYNOPSIS

```
linux/fs/file_table.c
static void put_last_free(struct file *file);
```

DESCRIPTION

This function will remove `file` from the file table and insert it again at the end. You can access by `first_file->prev`

AUTHOR

Linus Torvalds

remove_file_free

`remove_file_free`—Remove a file table entry from the linked list.

SYNOPSIS

```
linux/fs/file_table.c
static void remove_file_free(struct file *file);
```

DESCRIPTION

This routine removes the file from the table. This is used mostly for moving a file to the “end” of the list.
